Development of a diagnostic device to predict clinically significant inflammation associated with cardiac surgery

By

Mohammed Yahya Majrashi

Supervisor: Professor. Terry Gourlay

This thesis is submitted in accordance with the regulations governing the award of the Degree of Doctor of Philosophy in Biomedical Engineering

Declaration

This thesis is the result of the the author's original research. It has been composed by the author and has been previously submitted for examination which led to the award of a degree.

Signed

Date :

Acknowledgement

I would like deeply to thanks my hero supervisor Professor. Terry Gourlay for his advice, support and help throughout my PhD studies at the University of Strathclyde. His wealth experience and knowledge in the cardiovascular area guided me to produce this piece of work. Without his vision, the project could not have begun.

I would like also to express my grateful thanks to Dr. Craig Robertson and Dr. Monica for their support over my writing up stage. Your recommendations and advices helped me to improve the quality of this work.

Thanks to Dr.Baker from chemistry department for his help and support during FTIR work.

Thanks to Professor.Serdar Gunydin and all colleagues at memorial hospital in Ankara,Turkey.

Thanks to my parents, my lovely wife and my children for their support and encouragements over my study.

Thanks to all my friends at biomedical engineering department for their support and encouragements.

I would like to acknowledge my sponsor (Saudi Food and Drug Authority) for their financial funding of my Doctorate study.

Figure and table permissions: where figures and tables have been included from other sources, permission has been obtained for their use and the original authors given due acknowledgment within the legend.

Abstract

Background

Cardiopulmonary bypass deployment is known to cause an inflammatory response during open heart surgery. Inflammation involves the activation of different cascades such as coagulation, the complement system and cytokines. Although the immune system is the body's key defense mechanism against external assault, it can be injurious to the patient when the immune system is over-expressed, particularly in cohort of patients that experience a heightened and uncontrolled response. This exaggerated response results in autoimmune injury and may lead to poor post-operative outcomes, such as systemic inflammatory response syndrome and multi-organ failure.

Aim of the work

This project was aimed to develop a predictive screening technology that enables clinicians to specify patients who may be at risk prior to open heart surgery. This project suggests a new approach to identifying these patients, through the development of a novel technology that will measure the extent of the inflammatory response following blood contact with extracorporeal systems. This work focuses on cardiopulmonary bypass, but the technology may also extend to other treatments and interventional modalities in which tissues, in particular blood, comes into contact with foreign surfaces.

Approach

A series of in-vitro studies on bovine blood were performed to investigate the role of two initiators of the inflammatory response (DEHP plasticised PVC and liquid DEHP itself) and the exaggeration of different pro-inflammatory cytokines levels. A

clinical study was then undertaken in open heart surgery patients to confirm the preliminary outcomes from the in vitro studies and to specify the most appropriate plasma marker that predict patients at-risk of developing SIRS (focusing on IL-6, TNF-α and C-reactive protein). The clinical study was aimed to outline the most appropriate initiator and measuring technique for cytokine concentration (ELISA versus Fourier Transform Infrared Spectroscopy (FTIR)) and we sought to establish a final design configuration of the proposed screening technology.

Results

The in vitro studies showed that both DEHP plasticised PVC and liquid DEHP are effective initiators of the inflammatory response. This was verified by the clinical investigations, and the data suggested that IL-6 with DEHP plasticised PVC is the most sensitive diagnostic marker that can identify patients prior to open heart surgery who are at risk of developing SIRS. Both analysing techniques (ELISA and FTIR) were shown to be suitable for the intended device development. However, FTIR – with its reduced complexity and processing time - was considered to be the best analytical modality for future ongoing development of the intended POC screening device. A basic prototype for this screening device (an activation chamber, separation and wicking membrane and device schematics) was developed and future work is necessary to deliver the device to the clinic.

Thesis outline

In chapter 1, Cardiopulmonary bypass system is explained in terms of the history, development and the essential integrated parts of the machine. In addition, a brief description about the pathophysiological issues with CPB was mentioned at the end of this chapter.

In chapter 2, we discussed the integration between the cardiopulmonary bypass and the inflammatory response over the surgery which leads to development of the systemic inflammatory response syndrome (SIRS). This syndrome was addressed in more detail including the onset of the syndrome, cellular and humoral pathway activation and the anti-inflammatory strategies used to attenuate the deleterious outcomes from SIRS.

Chapter 3: Hypothesis and the objectives of this work.

Chapter 4: Describing in-vitro methodology.

Chapter 5: Presenting the data from the series of in-vitro bovine studies. The results were expressed in terms of IL-6 and TNF-α levels.

Chapter 6: Describing the clinical study methodology.

Chapter 7: Clinical study data were presented in relation to the three tested molecules (IL-6,TNF-α and CRP). Further analysis was performed on the data to choose the most appropriate cytokine that can detect high risk patients prior to the surgery and specify the suited technology for measuring cytokine concentration (ELISA or FTIR) to be used in the device development stage.

Chapter 8: The proposed screening test technology was developed based on the significant outcomes from both laboratory and clinical studies.

Chapter 9: Discussion of the findings and the outcomes from laboratory, clinical studies and the device development stage.

Chapter 10: Overall conclusion and the future work recommendations.

Chapter 1

Cardiopulmonary bypass

(CPB)

1 : Cardiopulmonary bypass (CPB)

1.1 Introduction

Cardiovascular diseases are the leading cause of death globally. Different types of cardiac operations are performed every day in hospitals varying in complexity to treat several lesions such as coronary artery bypass graft, heart valve replacement and total heart replacement. Cardiopulmonary bypass (CPB) is a crucial technique employed in the majority of these operations (Punjabi and Taylor 2013). It takes over the function of the heart and lungs during the surgery to maintain the adequate circulation of oxygen and nutrients over the procedure.

1.1.1 Coronary artery bypass graft (CABG)

CABG is a common procedure that used CPB to treat the blockage of the coronary arteries. It diverts blood around an obstructed artery in order to improve or restore blood flow and oxygen to the heart. The left and right coronary arteries play a crucial role in the controlling of the supplied amount of oxygen to the body. If these arteries are blocked or narrowed, (risk factors include obesity, high cholesterol and smoking) blood flow is occluded and the patient may suffer from atherosclerosis. Patients with atherosclerosis after experience severe angina and are at risk of myocardial infraction. Hence, the surgical intervention in this situation involves grafting a vessel in the taking of a new vessel from the arm, chest or leg and attaching to the coronary artery below the blockage area.

1.2 Cardiopulmonary bypass history (CPB)

The concept of perfusing organs during surgery originated in the late $18^{th,}$ early 19^{th} century. Several studies on animal models were conducted to investigate the effectiveness of dynamic blood flow via organs (Belanger et al. 2002; Rickards and

Tzeng 2015). Subsequently, Lillehei reported a novel successful technology of cross circulation (figure 1), using a clinical study on 32 patients with cross circulation system (Lillehei 1993).

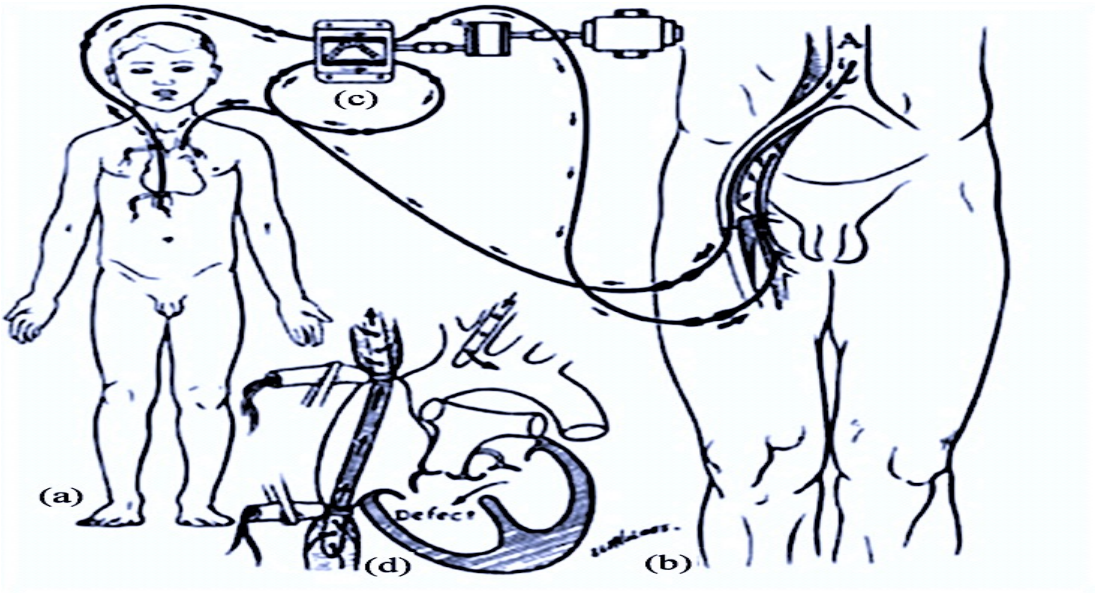

Figure 1: Cross circulation technology (a) the patients, (b) the donor, (c) motor pump and (d) close up of the patients heart. Basically, the adult's femoral artery was connected to the child's left artery. A single superior vena cava cannula was used in order to drain blood between patients. Also, a motor pump was used to control the blood flow and maintain the adequate blood volume during the procedure (Hessel 2015).

Dr Gibbon pioneered the development of CPB with his research group in the United States (figure 2). In 1931, he developed a pump oxygenator which would be a key mechanism in the technology. The first successful use of Gibbon's heart lung machine was on dogs (Gibbon Jr et al. 1954). 12 out of 20 dogs survived the surgery. In 1953, he attempted this in humans, and connected the patient to the CPB for 26 minutes in order to repair an arterial septal defect (Cohn 2003). After this successful operation, surgeons and bioengineers considered the technical feasibility of applying CPB to many conditions within the cardiac surgery, including open-heart surgery. Now, more than 1 million open-heart surgery operations are performed using CPB every year (Punjabi and Taylor 2013).

CPB uses a number of technologies (pumps and oxygenators). The first major development of CPB involved the use of roller pumps and bubble oxygenators were in the 1950s, and, in the 1960s, disposable oxygenators were developed to expand their blood capacity. In the 1970s, the first generation of membrane oxygenators and centrifugal pumps were introduced to CPB technology. Following these advancements, in the 1990s, researchers studied the post-operative outcomes that resulted from CPB in particular, the onset of an inflammatory response. This initiated major studies on the area of biocoating (Galletti and Mora 1995) (Edmunds 2002). Nowadays, CPB is considered to be the most effective and successful assisting device that can take over heart and lung function during surgical procedures. Technological iterations are still ongoing to optimise life support systems by reducing the mortality and morbidity rates (John W Mulholland 2012).

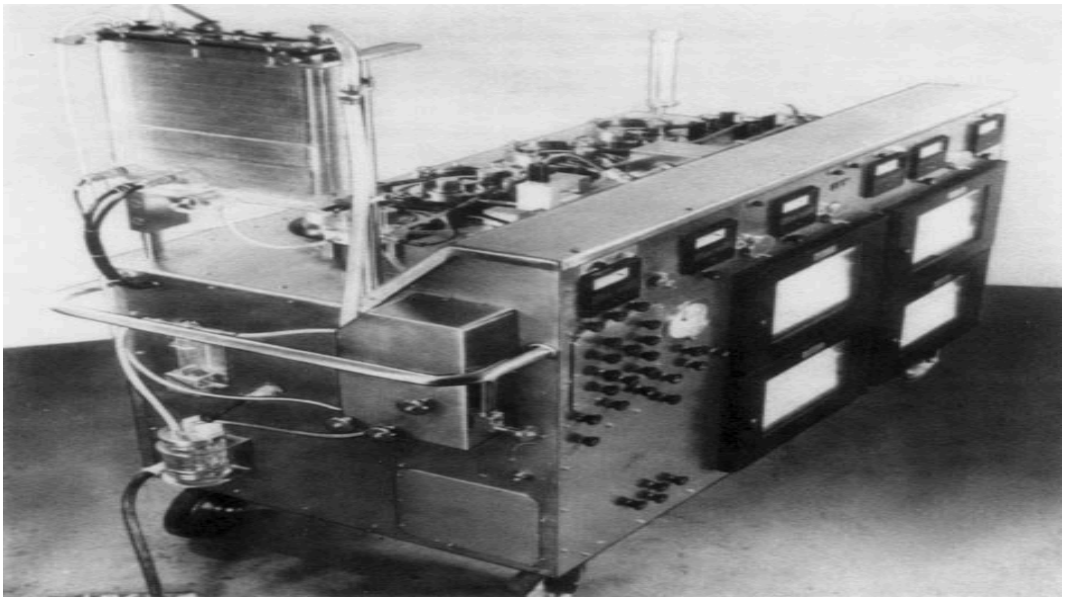

Figure 2:Gibbon's heart lung machine (Cohn 2003).

1.3 CPB circuit (Principle of operation)

The early preparation step before connecting the patient to CPB is blood anticoagulation. Patient's blood is heparinized in order to prevent blood clotting. The normal dose of heparin is between 300 and 400 IU/ kg (O'Carroll-Kuehn and Meeran 2007).Venous cannula is then connected to the heart via median sternotomy. Insertion pathways of the cannula include the femoral vein, axillary artery and both ascending and descending aorta.

Venous blood is drawn from the right atrium via a polyvinyl chloride pipe to the venous reservoir to perform two main functions: to filter the blood and act as a capacitance chamber to manage the acute volume shift resulting from the use of CPB. To achieve the adequate blood volume drainage via venous cannula, it is very important to select appropriate cannula radius size. Basically, high blood pressure with a small cannula diameter leads to turbulent flow of the blood according to Reynolds number (Machin and Allsager 2006). The correct position of the cannula also plays an essential role in the blood volume drainage. Practically, the adequate venous blood volume is achieved by releasing the venous line clamp and allow the pump to receive the adequate volume that play a crucial role in the elimination of the air embolism risk. Then, the venous blood is pumped via a roller pump to the blood gas exchanger in order to purify and oxygenate the incoming blood before returning to return it back to the patient. Inside the hollow fibre membrane chambers, blood is flushed through a hollow fibre membrane in order to allow blood gas exchange and purification of the deoxygenated blood. Finally, the purified blood is returned back to the patient via the arterial cannula. The schematic diagram below shows the blood flow cycle within the heart lung machine during the operation (figure 3).

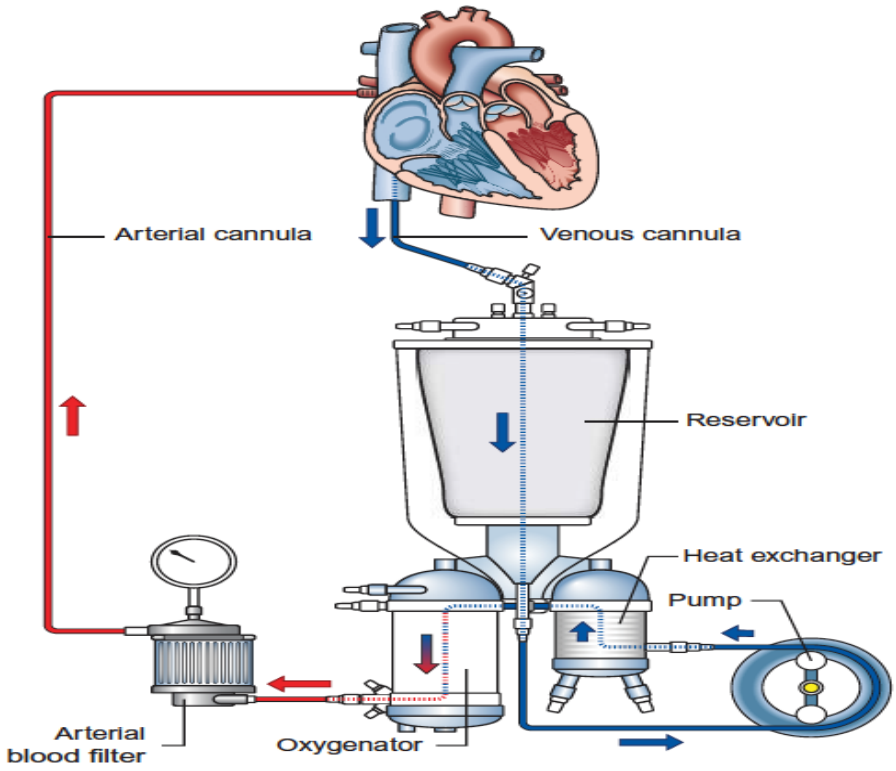

Figure 3:Cardiopulmonary bypass components(Punjabi and Taylor 2013) .

Tubing

CPB tubes are made from different materials (Poly vinyl chloride (PVC), silicon and latex rubber). PVC is developed by the formation of the polymer chain (Carbon-Chlorine), and this bond makes the tube rigid and strong. Therefore, a plasticizer is incorporated to PVC in order to enhance the flexibility of the tube and to make it softer. PVC is more sensitive to the temperature fluctuations, unlike silicon and latex rubber. However, PVC is still used commonly in medical applications due to its durability and acceptable level of hemolysis (Ma, Lu, and Gao 2002).

Arterial cannula

The arterial cannula connects the arterial side of the CPB machine and the patient. It works to transport the oxygenated purified blood from the machine to the patient.

There are different variations of cannula regarding thickness and size, and thin walled cannula is preferred due to its low resistance to blood flow.

Arterial filter

Arterial filters are one of the basic integrated CPB components. It is made from hydrophilic polyester material with an exposure area to the blood ranging from 400-800cm^2(Hawkins et al. 2010).

Arterial filter acts to remove air and other detritus from the purified and oxygenated blood before returning to the patient (Kaza et al. 2003). This feature continues to work with CPB system with no direct return of shed blood. However, the new developed life support systems-such as minimized extracorporeal circulation-consists of a closed system that has air removal and automated blood flow control. This new features reduces the need for using arterial filter in the circuit (Brian 2008).

Venous cannula

This cannula is placed in the right atrium of the heart. The venous reservoir is placed 40cm to 70 cm below the heart. Basically, gravity plays an essential role in draining blood to the system. In terms of the venous cannula, it is made of flexible plastic in order to avoid the risk of kinking. The disadvantage of this cannula is the inability to stop all blood and its interference with the right atrium.

Currently, Smart Cannula is considered as the best optimal design used in a variety of applications in the medical field (Mueller, Mallabiabrena, et al. 2002). As seen in figure 4, the design allows self-expansion of the cannula within the vein which leads to enhanced flow rates and improved vascular access to the patient(Jegger et al. 2002; Jegger et al. 2003).

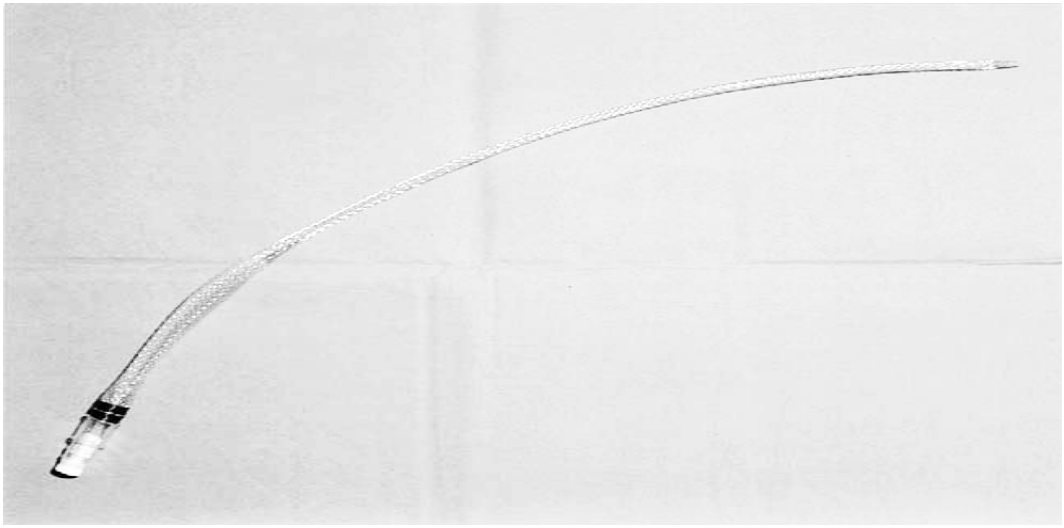

Figure 4:Smart Cannula(Mueller, Tevaearai, et al. 2002) .

Venous reservoir

The venous reservoir is considered as an essential part of the whole CPB system. It is performing two main functions: accumulate the coming blood from the patient's vein and remove any air/ bubbles from the venous blood. It is connected between the patient and the arterial pump. The blood is drained by the effect of gravity into the oxygenators for oxygenation purposes and removing the carbon dioxide.

Clinically, there are two types of venous reservoir (open and closed). Closed reservoir is considered as the best standard type in the market due to its high biocompatibility rather than open system (Schönberger, Everts, and Hoffmann 1995).

Pumps

During CPB, the deoxygenated blood is pumped to the machine for oxygenation and returning back to the patient via a mechanical pump.The pump configuration considers the relationship between two important factors (resistance and pressure) in order to achieve a constant blood flow. The Hagen-Poiseuille equation is described below:

Blood flow rate= Pressure / resistance.

There are two types of pumps: roller and centrifugal pumps. Both types are widely used due to their accuracy and the ability to generate different blood flow rates (Machin and Allsager 2006).

A roller pump is a curved metal shape surrounded by length of PVC and silicon tube. This pump is based on the forward blood flow (positive displacement device). A centrifugal pump instead consists of a plastic cone with a vaned impeller. This cone is powered by electrical motor that generates centrifugal force which is converted into kinetic energy to deliver the blood through the circuit. It has many advantages compared to the roller pump, such as reducing the likelihood of rupture and the disconnection of other circuit components, flow obstruction, and reducing blood trauma.

Oxygenators

Oxygenators take over the lung function to provide purified blood to the patient (figure 5). Historically, the first used oxygenator in the theatre was by Dr. Gibbon in 1953. Bubble oxygenators were used during that period. However, the increase in the number of patients and demand on OHS led to an increased demand of developing a new membrane technology which can enhance the surgical procedure.

In 1980, Mitsubishi introduced a new membrane technology that comprises three layers (polyurethane and polypropylene). This membrane has three main advantages: firstly, high productivity, secondly self-supporting and thirdly, high recovery rate.

In some cardiac operations, a micro filter bubble trap is added to the arterial outflow in order to achieve high levels of filtration before returning the blood to the patient. (Punjabi and Taylor 2013).

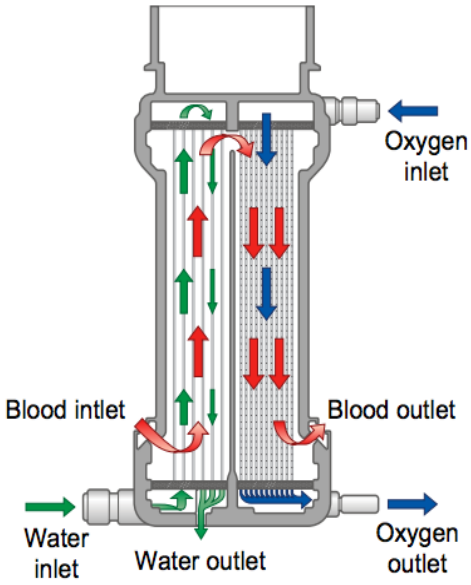

Figure 5:Membrane oxygenators workflow Deoxygenated blood enters through the blood inlet port and comes in contact with hollow fibre membrane for blood-gas exchange. Finally, the purified blood leaves through the blood outlet port (Punjabi and Taylor 2013).

Heat exchange

Maintaining acceptable temperature levels during surgery plays a crucial role in eliminating the risk of developing unwanted complications with CPB.(Stump 2005) reported that the optimal perfusion temperature is between (32-35°C).

Heat exchangers control temperature via an integrated heater and cooler device attached to the oxygenator. This device is composed of a water circuit in addition to the blood circuit. Adjusting the temperature at the water circuit manually during the surgery can thus control the blood temperature (Schmidt et al. 2003). In relation to cardioplegia cooling system, mixed blood/ crystalloid is delivered from CPB to the aortic roots every 15 to 30 min during the aortic cross clamping procedure in order to maintain heart arrest and hypothermic condition over the surgery. The cardioplegic dosage can be administered based on the patient's weight and body surface area (Durandy 2015).

Anticoagulants

CPB components must be coated to increase biocompatibility with the blood. Direct contact between the blood from the patient and the tube materials lead to the activation of inflammatory cascades such as complement and coagulation cascades. Therefore, an anticoagulant is necessary to prevent clotting factors during surgery that are associated with these cascades (O'Carroll-Kuehn and Meeran 2007). Heparin is a popular anticoagulant that used in different operations. The required amount is 300 units/kg, and this is given to the patient and to the CPB circuit (Michelsen et al. 1996).

Priming solutions and CPB circuit

It is essential to use prime solutions and fluids in CPB to prevent any risk of air embolism. The required volume of the priming solutions is determined by the caliber and length of the tube used in both sides (venous and arterial) and the CPB design. The normal priming solution range for adult patients is between 1400 -1800 ml (Gu and Boonstra 2006).

Priming solutions classification

Choosing the appropriate prime solution for CPB has been a concern for a number of decades (Boonstra and Gu 2004). Basically, priming solutions can be classified into two groups: crystalloids and colloids (Gu and Boonstra 2006). The prime solution varies throughout different medical centres based on the cost and ease of use. A comprehensive survey was conducted in 31 cardiac centers in United Kingdom and Ireland showed that surgeons recommended using crystalloids during cardiopulmonary surgery (Lilley 2002).

Crystalloids

Crystalloids are considered an ideal priming fluid due to similarities in tonicity and electrolyte composition with blood plasma. Tonicity is crucial due its role in the preventing red cell lysis during CPB. There are three types of crystolloids based on the solute concentrations and its relation to the plasma: isotonic(solute concentrations are equal to the solute concentration of plasma, hypotonic(less than the solute concentration of plasma) and hypertonic(greater than the solute concentration of plasma) (Frumento and Bennett-Guerrero 2008).

Dextrose

Cooley and colleagues stated that using dextrose with priming solution lead to improved clinical outcomes(Cooley, Beall, and Grondin 1962). It is considered as one of the first crystalloid priming solutions used for CPB. It has a beneficial effect in reducing mechanical damage to the red blood cells and improving post-operative outcomes (Quinn et al. 2006).

Mannitol

Mannitol is a hypertonic solution used widely in clinical practice in order to stimulate diuresis. Adding 5% mannitol may help to reduce the impact on organs such as kidney and reduce the effect of having renal failure after the surgery. Fisher and his research team conducted study to determine the effect of mannitol in the post CPB renal functions, and it showed an improvement in renal functions after the operation (Fisher et al. 1998).

Colloids

Colloids contain 4.5 % albumin, gelatins and starches. These solutions are used in CPB due their role in the decreasing the colloid oncotic pressure. This reduction leads to eliminating the shift of water and other fluids to the intracellular spaces.

1.4 Pathophysiology of the CPB

Although CPB administration is considered a successful technology in most cardiac surgeries, it can lead to significant pathophysiological processes with regards to: haemodynamics,hypothermia and blood cell activation (Smith, Smith, and Taylor 1993).

Haemodynamics

The flow rate during CPB is adjusted by the perfusionist. Blood flow rate during CPB ranges from 2-2.5 l/m^2 at normal temperature but it decreases as the temperature decreases(Cook et al. 1997; Schima et al. 1997). It is vital to achieve the moderate flow rate by CPB in order to avoid the risk of blood cell trauma. The used of moderated hypothermia during cardiac surgery leads to reduced blood flow rate in the CPB system. Practically, maintaining a lower temperature can lead to a decrease in the oxygen consumption rate. For example, lowering the temperature from 37°C to 20 °C resulted in oxygen reduction to 120 ml/m^2 per minute at flow rate 2.4 l/m^2(Smith, Smith, and Taylor 1993).

Hypothermia

Hypothermia may lead to an increase in the ischaemic thresholds. The optimal temperature is achieved during CPB by using either an external cold solution around the heart or a cardioplegic technique (cold solution infused into the coronary circulation).

Blood cell activation

CPB requires patient's blood to come in contact with a large surface area during the 1-2 hour procedure. This contact may trigger the activation of different inflammatory cascades and inflammatory mediators that contribute to the development of an inflammatory response syndrome and other deleterious effects (Gourlay et al. 2001). This is predominantly due to blood's interaction with surface, which is normally DEHP Plasticised PVC.

1.5 Summary

1. CPB is a life support system used in cardiac surgery since 1953. It consists of many integrated parts including roller pump and oxygenators. It takes over heart and lung function throughout the surgery
2. CPB system is managed by a professional perfusionists and directed over the surgery by surgeons. Although, it is considered as the gold standard technology in the cardiac operations due to its efficacy and lower mortality and morbidity rates, it is associated with number of complications that may produce deleterious outcomes. The following chapter will discuss these complications in details, in relation to the development of an inflammatory response.

Chapter 2: Cardiopulmonary bypass and the development of inflammatory responses

2 : Cardiopulmonary bypass and the development of inflammatory responses

2.1 The concept of inflammation

Inflammation is the body's adaptive response to insult and injury (Majno and Joris 1996). This response varies from normal to severe. The first description of inflammation was presented by a Roman physician called Celsus in the first century, who stated that inflammation is characterised by four common signs which are redness, heat, pain and swelling. Inflammation has been recognised throughout the ages as the defence of the body against the foreign insult, from Galen in the 3rd centaury to John Hunter in the 18th centaury.

At the beginning of the 20th century, the concept of inflammation was expanded by immunologists who demonstrated the essential role of both antibodies and antigens in the developing of the inflammatory cascades (cellular and humoral)(S.H.Ferreira 1978). Subsequently, there was a noticeable understanding of inflammation and its role in the prognosis of different pathogens. They highlighted the importance of chemical mediators in the inflammatory cycle and how they affect controlling the development of disease.

The inflammatory response level varies from patient to patient based on the severity of the insult and other factors related to the patient's physiology. The early stage of inflammation is characterised by three processes which are: changing the calibre of flow in small blood vessels, increased vascular permeability, and increased adhesion molecules with vascular endothelium interactions.

2.2 Inflammation

There are six common signs of the inflammation (figure 6) which are:

- Fever, which means an increase in the temperature of the body and can be detected under the skin. This results from the increase of blood flow at the inflamed /injured site.
- Swelling, which results from the accumulation of fluid under the skin due to the comprehensive process of the inflammatory responses.
- Tiredness is characterized by increased inactivity and feeling of lethargy.
- Pain normally results from stretching and distortion of the tissue as a by-product of the inflammatory response (such as oedema)
- Loss of function
- Redness at the site of inflammation.

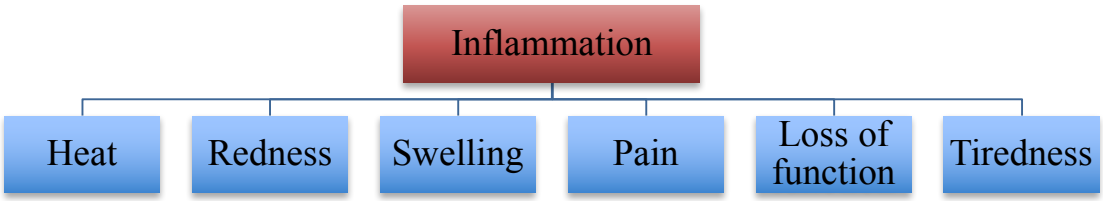

Figure 6:Cardinal signs of inflammation.

2.2.1 Causes of inflammation

Although inflammation is a normal reaction at the site of injury, the overexpression of inflammatory mediators can result from a number of factors (microbial infections, hypersensitivity, physical and chemical agents and necrosis).

Microbial infections

The majority of inflammatory diseases are triggered by microbes such as viruses, bacteria, fungi and parasites. Viral infections spread to the intracellular cells and lead to cell death or sometimes explosion the cells (phagocytosis and apoptosis). Phagocytosis is the process of ingesting the cells and particles, whereas apoptosis is a programmed cell death which can be initiated through two main pathways: intrinsic (cell death by the cell itself) and extrinsic (cell death by a signal from other cell) (Elmore 2007).

Hypersensitivity

This refers to an excessive reaction of the immune system, and it is divided into four types: immediate, antibody mediated, immune-complex mediated and cell mediated (Sherman 1968).

Type 1: immediate reaction

This is the rapid reaction to external stimuli. It involves skin(eczema), eye reactions, and other common diseases such as asthma. This response usually takes 15-30 minutes following stimulation but in exceptional cases the response may delayed to 10-12 hours (Samuelsson 1983; Ghaffar 2006).

The mechanism of type 1 hypersensitivity is characterized by the mediation of immunoglobin IgE (a specific antibody produced by the immune system which is an over reaction to an allergy). This mediation leads to initiate the activation of specific inflammatory cells (mast and basophil immune cells).

Type 2: antibody mediated

This is characterized by the process of an antibody binding to a specific targeted antigen which leads to the process of cell destruction. It plays a pivotal role in

several diseases such as rheumatic heart disease and autoimmune hemolytic anemia. Moreover, the reaction time of this type ranges from minutes to hours.

Type 3: Immune complex disease

This is defined as the binding of antibodies to a specific soluble antigen in order to form the circulating immune complex. This reaction is classified as general (such as serum sickness) and individual (such as extrinsic allergic alveolities). The normal onset of this response occurs from 3 to 8 hours post-exposure.

Type 4: Delayed type hypersensitivity

This is known as cell mediated hypersensitivity due to its effect on cell structures. This type contributes to the development of common diseases such as tuberculosis, toxoplasmosis and blastomycosis. The onset time of this ranges from 48-72 hours (Ghaffar 2006).

Physical and chemical agents

Inflammation may occur from trauma and exposure to chemicals or physical agents such as radiation and burns. These agents and others provoke the inflammatory mediators at the site of injury via different inflammatory pathways including cellular and humoral cascades.

Necrosis

Necrosis refers to tissue's death due to a lack of oxygen and nutrients. This occurs because of a limited blood flow at the site of injury due to the exposure to different factors that can cause cell death such as infections, trauma and exposure to toxins (Kroemer et al. 2009).

2.2.2 Acute phase of inflammation

The acute phase of inflammation occurs within seconds after injury and damage to the tissue. The damage may be physical to the body or involving the activation of the immune system and other immunity cellular cascades. This phase increases blood flow to the site of the injury, increases permeability of proteins and fluid to move into the interstitial spaces.

2.2.3 Chronic inflammation

Chronic inflammation refers to an inflammation over a long period of time (weeks to months). It can be divided into two groups: granulomas and non-granulomas depending on the stimuli agent (infection or non-infection)(Majno and Joris 1996). Chronic inflammation is productive and proliferative, and it involves the adaptive immune system (subsystem from the overall immune system that is composed of different specialized cells to prevent the pathogen growth) and contributes to many other diseases such as cardiovascular disease, diabetes, atherosclerosis, obesity and rheumatoid arthritis.

Clinically, the symptoms of chronic inflammation are similar to the acute inflammatory symptoms. Some of the chronic inflammatory symptoms start at early onset and progress slowly. For example, irritating pain, allergy, asthma, fatigue and skin problems are common chronic inflammation signs.

Cytokines, a large group of proteins, peptides or glycoproteins secreted by specific cells of the immune system, are strongly associated with acute and chronic inflammation. Tumor necrosis factor-α (TNF-α) and interleukin-1 (IL-1) cytokines stimulate the production of collagenase and other enzyme which accumulate at the

site of injury in order to repair the tissue damage and enhance the healing process (Verschure and Van Noorden 1989).

2.3 Basic components of the blood

2.3.1 Red blood cells (erythrocytes)

Red blood cells (RBCs) are considered the essential part of blood. They represent approximately 45% of the whole blood volume and contain two important elements of the blood (haemoglobin and iron). RBCs play a crucial role in carrying oxygen and removing unwanted elements such as carbon dioxide.

In the context of CPB, RBC hemolysis (rupture of RBCs) is considered as one of the predominant problems that contribute to deleterious outcomes. Many factors contribute to the damaging of RBC structure and cause hemolysis such as shear stress, pressure, blood exposure time to the non-endothelial surface of the CPB tube and other cellular factors (Vercaemst 2008; Vieira Junior et al. 2012).

Patients who suffer from hemolysis during CPB may at risk of developing unwanted complications during the surgery (Yousafzai et al. 2010).

2.3.2 White blood cells (leukocytes)

White blood cells (WBCs) are immune cells circulating in the blood to protect the body from foreign attack and infections (bacteria, viruses, parasites). WBCs are classified into two main categories based on structure (presence of cytoplasmic granules): granulocytes and agranulocytes.

Granulocytes are granules containing white blood cells (neutrophils, basophils and eosinophils). Conversely, agranulocytes do not have cytoplasmic granules in their structure. The two common types of a granulocytes are monocytes and lymphocytes.

Monocytes are the largest WBCs in the blood, and their main function is to carry out phagocytosis of foreign particles. A smaller subtype of WBCs are lymphocytes, which are formed in bone marrow. There are three main types of lymphocytes: T cells (cell mediated immunity that mature in the thymus gland), B cells (humoral immunity that mature in the bone marrow) and natural killer cells (cytotoxic). Both T and B cells types produce antibodies to attack a specific targeted antigen and destroy it (Abul K.Abbas 1991).

2.3.3 Platelets

Platelets are fragmented cells that circulate in the blood and bind together when there is an exciting injury and damage to the blood vessels. They originate in the bone marrow with normal range between 150,000 and 450,000 per milliliter of the blood. If the patient's platelets number is lower than 150,000, the condition is called thrombocytopenia (in which the patient experiences fatigue and weakness) while if the number is over 450,000, it is called thrombocytosis (which often presents with inflammatory disease) (Michelson 2006).

In the context of CPB, there are a number of factors that trigger the activation of the platelets, such as hypothermia, shear forces, blood contact with non-endothelial surfaces and the release of endogenous chemicals (Day et al. 2002; Day, Landis, and Taylor 2004; Weerasinghe and Taylor 1998). It was reported by Day and colleagues that platelet activation during CPB promotes the process of neutrophils adhesion and transmigration by attaching the activated platelets to the vascular wall of the endothelium (Day and Taylor 2005).

2.4 Inflammatory cells

2.4.1 Neutrophils

Neutrophils are immune cells which are made in the bone marrow and circulate in the blood stream. They form around 70% of the white blood cells and considered as the first defense line against any foreign attackers to the body (Kumar and Sharma 2010). A series of inflammatory cascades promote the activation of neutrophils cells such as complement mechanisms, endotoxins and cytokines (Asimakopoulos et al. 1999).

2.4.2 Basophils

Basophils are inflammatory mediator cells described as a small population of peripheral blood leukocytes that contain cytoplasmic granulocytes. They play an important role in the development of inflammatory reactions to stimuli, and they are vital cellular components that trigger inflammatory cascades. During basophilic activation by internal or external stimulation, there is a secretion of a chemical called histamine. This chemical enhances the vascular permeability of basophils to migrate at the local site of injury.

2.4.3 Mast cells

Inflammatory cells play an important role in the development of the inflammatory response cycle. Mast cells are derived from the haematopoietic progenitor cells and circulate in the blood in an immature form (Urb and Sheppard 2012). These cells are found in the most of body tissues, specifically located on the outer surface layers (such as the skin) to enable contact with external stimuli. When the mast cells activate, they release different pro-inflammatory cytokines to the blood, and they can also be activated by thrombin, a crucial chemical in the coagulation cascades.

2.4.4 Monocytes

These are incompletely differentiated phagocytes in the blood stream. During the activation stage, monocytes settle in the tissue and are known as macrophages. They can be activated via different stimulation factors such as complement, endothelial cells, endotoxins and the presence of pro-inflammatory cytokines. The degree of inflammatory damage to the organ is related to the accumulation of the macrophages in the skin and the tissue (Ernofsson, Thelin, and Siegbahn 1997).

2.5 Immune system and inflammatory responses

The immune system plays a crucial role in the initiation of inflammatory responses. Activation of both cellular and humoral cascades leads to the secretion of pro-inflammatory and anti-inflammatory cytokines which promote the inflammatory mediators in the blood.

The factors that can lead to trigger the inflammatory responses are classified into nonspecific and specific factors. Surgical trauma, hypothermia and blood loss are nonspecific factors, while CPB activates the inflammatory mediators specifically via three different mechanisms: contact between the blood and the non-endothelial surface of the PVC tube, ischemia reperfusion because of aortic cross clamping; and the release of endotoxins (Ebadi et al. 2015; Warren, Smith, et al. 2009; Jofré et al. 2006; Hall, Stafford Smith, and Rocker 1997). These factors activate multiple humoral and cellular cascades (neutrophils, complement, coagulation and killikrein) which contribute to the initiation of the immune system to release pro-inflammatory and anti-inflammatory cytokines and may ultimately trigger systemic inflammatory response syndrome (Figure 7).

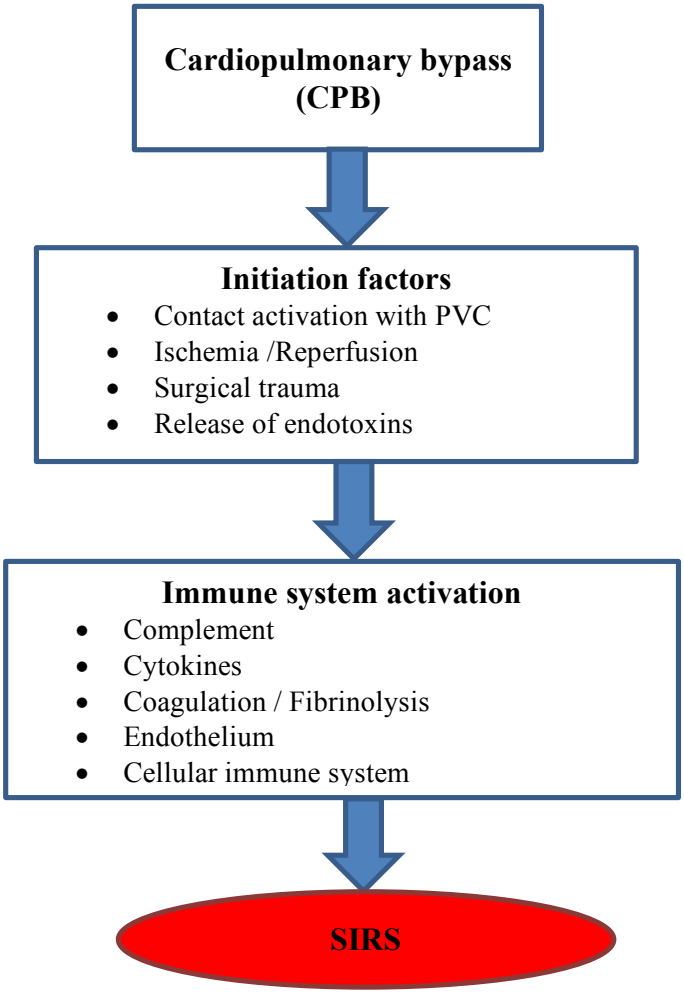

Figure 7:Schematic diagram of the sequences of events that lead to the development of systemic inflammatory response syndrome SIRS. Adopted from(Laffey 2002).

2.6 Potential trigger of inflammatory responses during CPB

2.6.1 Endotoxins

Endotoxins are one of the most potent known activators of innate immunity of the inflammatory response. The main source of endotoxins are the gram negative bacteria cell wall (Jaffer 2010; Ohri et al. 1991). Lipopolysaccharide molecules (LPS) are considered as the essential components of gram negative bacteria. The combination between LPS and other plasma proteins leads to stimulate the secretion of a series of pro-inflammatory cytokines such as IL-6 and TNF-α. Several studies demonstrated the strong correlation between the presence of endotoxins in the blood

and the post-operative complications. For example, a study on 100 patients with sepsis confirmed the presence of gram negative bacteria in 12% of those patients (Willatts, Speller, and Winter 1994). Riddington and colleagues stated that 40% of patients admitted for open heart surgery experienced increasing levels of endotoxins (Riddington et al. 1996).

2.6.2 Ischemia and reperfusion injury

During cardiac surgery operations with the use of CPB, ischemia occurs because of the stopped circulation of blood to the living organs such as kidney, liver and brain. This triggers the secretion of unwanted substances from these organs to the blood which results in the formation of ROS (reactive oxygen species). The major source of ROS is neutrophils. It contributes to cellular damage, inducing of adhesion molecules and inflammatory cytokines (Den Hengst et al. 2010).

Reperfusion occurs when the blood return back to the living organs after a period of ischemia and lack of oxygen (Schofield et al. 2013). Following reperfusion, neutrophils mediate the vascular endothelium interaction with leukocytes that mediate the generation of poor post-operative outcomes (Angus et al. 2004). In addition, several studies demonstrated abnormalities of pro-inflammatory cytokines (IL-6 and TNF-α) following reperfusion. TNF-α levels have been shown to increase following 3 hours of bilateral lower limb ischemia in rats and increased 1 hour after reperfusion(Yassin et al. 2002). Moreover, a clinical study performed on patients undergoing open heart surgery demonstrated that both TNF-α and IL-6 levels were increased following reperfusion (Edrees et al. 2003).

2.6.3 Oxidative stress

It is defined as the imbalance between the release of free radicals and the ability of the body to mitigate the harmful effects caused by these free radicals. It occurs when there is a significant uncontrolled secretion of reactive oxygen species (ROS). Inflammatory responses over CPB procedure trigger the secretion of ROS and the increase of oxidative stress. Also, pre-operative diseases such as diabetes may provoke the excessive secretion of oxidative stress and ROS (Giustarini et al. 2009). Haemolysis, ischemia, reperfusion and the activation of neutrophils during the use of CPB play a crucial role in the oxidative stress and stimulation of pro-inflammatory cytokines (figure 8) (Zakkar et al. 2015).

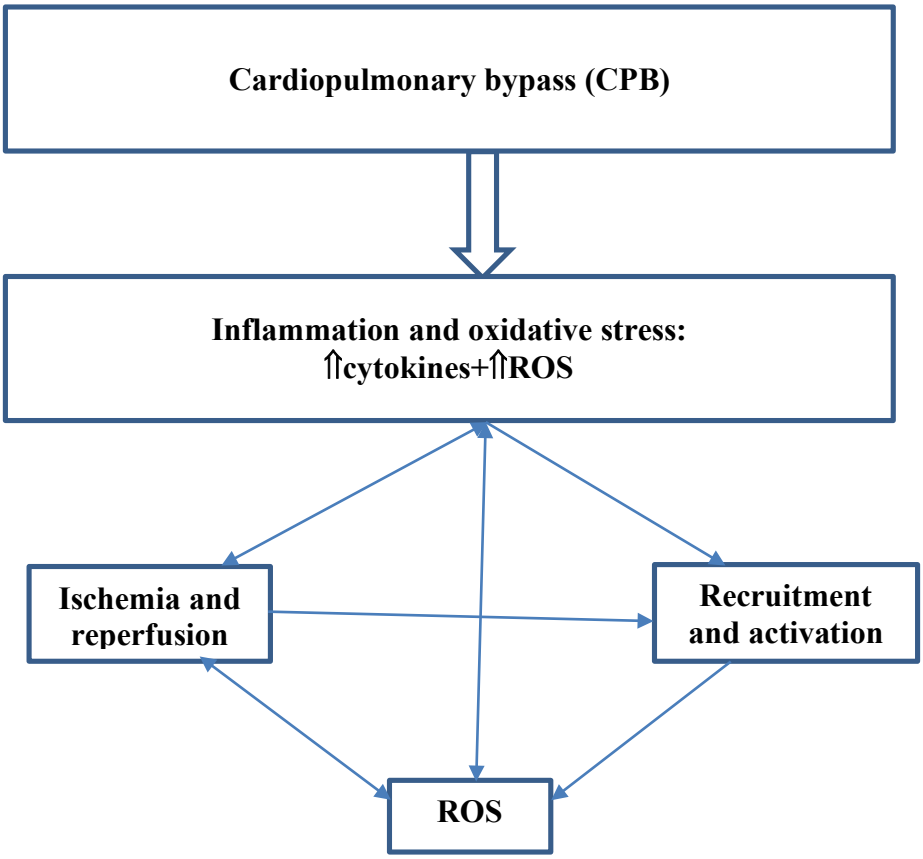

Figure 8:Inflammatory and oxidative stress during CPB. Adopted from (Zakkar et al. 2015).

2.6.4 Anticoagulants

Although anticoagulants such as heparin are considered as an important factor in the blood clot during the surgery, they can be associated with a number of complications post-surgery. A clinical study was conducted on 32 patients who were admitted for open heart surgery using CPB. 12 patients developed systemic inflammatory response syndrome whereas 20 patients had normal post-operative outcomes. The study investigated the relationship between heparin and the complications after the surgery. The result showed a strong correlation between the post-operative complications and reduced intraoperative heparin dose (Feindt et al. 2005).

2.6.5 DEHP plasticised PVC and the trigger of inflammatory cascades

Plasticised PVC is a blood contacting biomaterial. It is involved in widespread applications in the medical field such as storage bags, catheters and tubing. In the context of CPB, DEHP plasticised PVC tubes play a pivotal role in the initiation of different cellular and humoral inflammatory cascades (Gourlay et al. 2003). Several clinical studies reported the significance of DEHP plasticised PVC when it comes in contact with the blood. Takashi and colleagues conducted a clinical study on sixteen patients undergoing elective coronary artery bypass grafting. The patients were divided into two groups (group A had DEHP plasticised PVC tube in the CPB circuit and group B had non DEHP plasticised PVC). Blood samples were taken before anaesthesia induction and after the termination of CPB. The study concluded that using non-DEHP plasticised PVC tube reduced the initiation of inflammatory cascades(Takahashi et al. 2008).Also, it was reported that the reduction of plasticizer surface of PVC lead to decreased fibrinogen adsorption (Zhao and Courtney 1999).

2.7 Cellular pathway of inflammatory responses

It involves endothelial cell (a type of epithelium that from an interface between blood and the vessel wall) and leukocytes.

Endothelial cells are activated by a variety of agonists such as cytokines, thrombin and C5a. IL-1β and TNF-α pro-inflammatory cytokines stimulate the expression of P and E selectins (proteins that mediate the migration of cells to sites of inflammation) within a short period of time (2-4 hours) (Etzioni 1996; Kraft et al. 2015).

Leukocytes and endothelial cell interaction

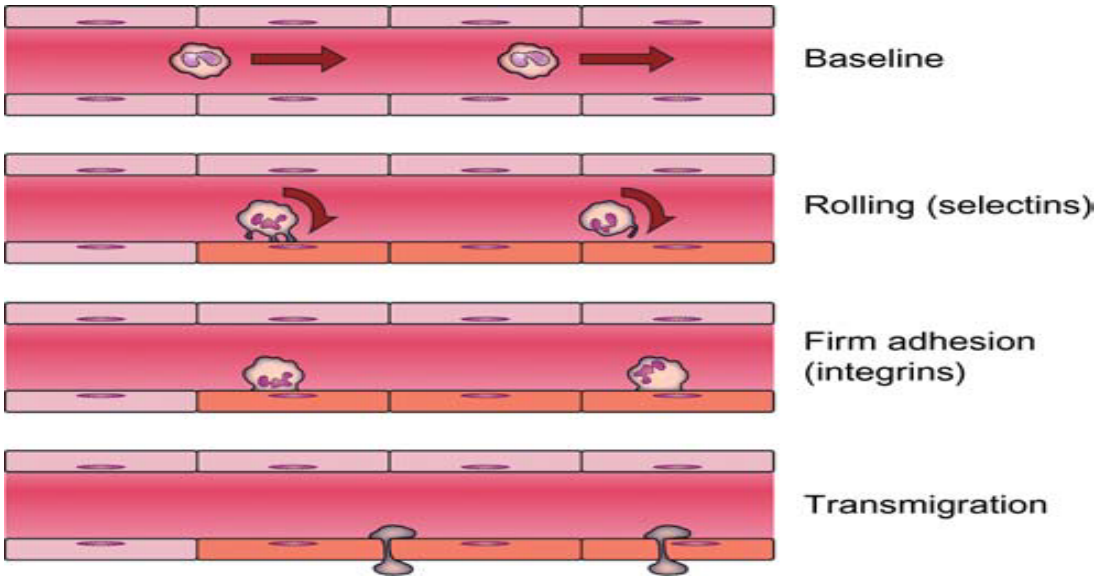

Figure 9:Adhesion molecules phases (Punjabi and Taylor 2013).

The movement of leukocytes, out of the circulatory system to the site of injury is known as leukocyte extravasation. This process occurs according to the following phases.

Phase 1: Attachment (early phase)

Resident Macrophages at the injured area releases pro-inflammatory cytokines (such as IL-1 and TNF-α) into the blood stimulating endothelial cell for adhesion process. Both expression of intracellular adhesion molecule1(ICAM1) and vascular cell

adhesion molecule1(VCAM1) play a cruical role in the binding of leukocytes to the endothelial cells' surfaces and the initiation of trafficking to the extravascular space(Ley et al. 2007; Patel, Cuvelier, and Wiehler 2002)

Phase 2: Rolling of leukocytes

This stage is stimulated by members of the selectin family-selectin L, selectin E and selectin P (Albelda, Smith, and Ward 1994). All selectins have a binding affinity (refers to the measurement of the strength attraction between receptor and ligand): oligosaccride, polysaccride and sulphate polysaccride and lipids.

Slow rolling of leukocytes

Following inflammation, the leukocytes rolling velocity decreases (average between 5 and 10 micrometers per second)(Jung and Ley 1999). Release of E selectin from the endothelial cell and CD18 integrins on the rolling leukocytes are essential to pursue this phase.

The aim of this phase is to promote the contact between leukocytes (neutrophils) an the endothelial cell which lead to further activation by chemokines and other pro-inflammatory cytokines (Muller 2013).

Phase 3: Firm adhesion

After the rolling phase, leukocytes adhere to the blood vessels under a flow condition. The process starts from the releasing of chemokines by macrophages which promotes the activation of leukocytes on the endothelial cells surface. This mechanism also motivates and P and E selectins with integrins to upgrade and move from the low affinity binding with ligands to high affinity binding state (Muller 2003).

Phase 4: Transmigration

Leukocytes migrate across the barrier during the resting condition of the endothelium. This penetration of the basement membrane involves two mechanisms(mechanical force and proteolytic digestion of the membrane)(Sorokin 2010).

2.8 Humoral pathways of inflammatory responses

Humoral immunity is defined as the aspect of immunity that is mediated by series of macromolecules such as cytokines, complement proteins and coagulation pathways.

2.8.1 Complement system

The word 'complement' refers to a set of proteins that cooperate with the immune system in order to eliminate blood and tissue pathogens. It represents one of the most powerful defense systems against any external and internal insult. Complement systems may act to bind and mediate the phagocytes while other complement proteins elicit the inflammatory response and induce the releasing of pro-inflammatory cytokines into the blood.

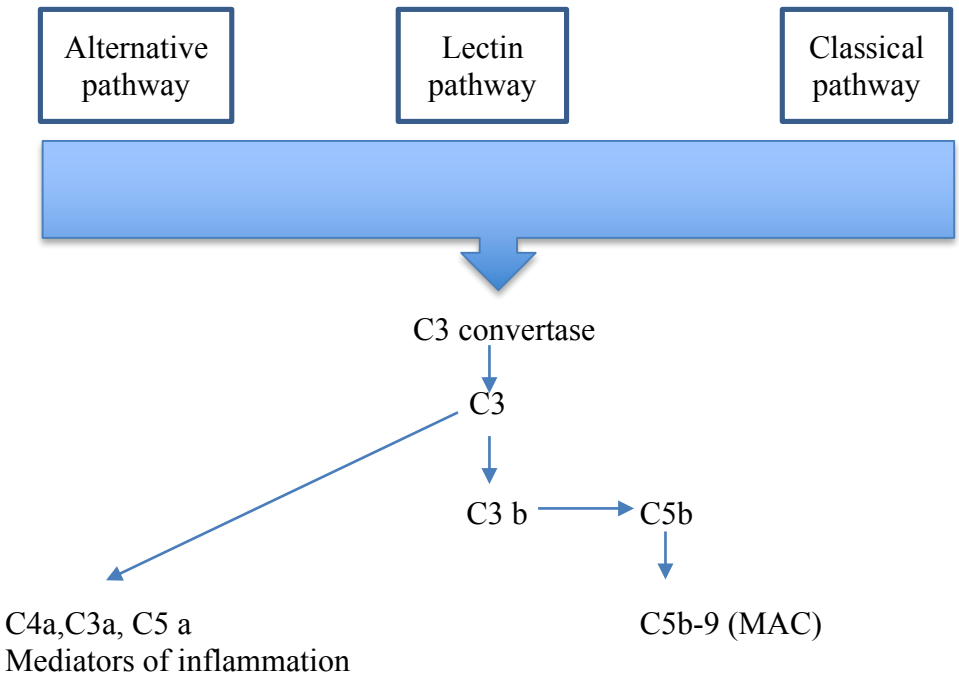

Figure 10:Complement system pathways. Adopted from (Thurman and Holers 2006).

The complement cascade is activated during CPB, ischemia-reperfusion and heparin neutralization with protamine (Laffey 2002). It is considered to be the early mechanism that triggers the acute inflammation phase and other inflammatory cascades. The activation of the complement system is performed via three different pathways (figure 10): classical pathway (activated by binding antibodies to antigens), alternative pathway (activated by the microbial cell surface) and lectin pathway, (activated by plasma lectin)(Day and Taylor 2005).Inactive form of the complement system, there are 9 components starting from C1-C9 while during the activation phase the number increased to over 20 cleavages.

Complement protein functions can be classified into seven groups, which are :

1. Initiator complement components: the protein initiates the complement cascade via binding to a specific soluble.
2. Enzymatic mediators.

3. Membrane binding components.
4. Inflammatory mediators: complement components enhance the supply of blood to the site of the injury via binding to the receptors in the endothelial cells. They also attract other cells to migrate and move to the injury site.
5. Membrane attack proteins.
6. Complement receptor proteins.
7. Regulatory complement components.

Complement Pathways

These pathways lead to the cleavage of C3 convertase (Rittirsch, Redl, and Huber-Lang 2012). Alternative pathways play a role in the defense against the infection while the classical pathway is involved in the clearance of the pathogenic factor (Charchaflieh et al. 2012).

As seen in figure 10, the classical pathway is initiated by antibodies binding to C1 and it is considered as part of the adaptive immune system. It leads to the formation of antigen-antibody complex C3 and C5 with the production of C3b and C5b. Moreover, the classic pathway produces the anaphylatoxins C3a and C5a.

The formation of anaphylatocxins play a crucial role in the acute inflammatory cascades such as vasodilation, leukocyte activation and adhesion molecule activation (Asimakopoulos 1999).

The activation of the alternative pathway is promoted and increased by the presence of a fungal and bacterial wall. It also depends on the change of specification of C3(Frank 1987). Alternative pathway leads to the formation of C3 convertase and C5. The two components join together to form the C5a and C5b. Further interactions occur to form finally the product C5b-9 which is called membrane attacking

complex(Tegla et al. 2011).The lectin pathway is activated by the binding of mannose-binding lectin (MBL) to mannose residues on the pathogen surface.

2.8.2 Coagulation – fibrinolytic cascade

Coagulation mechanism

Blood coagulation refers to a series of processes to stop the bleeding (haemostasis) at the site of injury, and can be achieved via two main haemostasis phases primary and secondary (figure 11) (Palta, Saroa, and Palta 2014).

Primary haemostasis

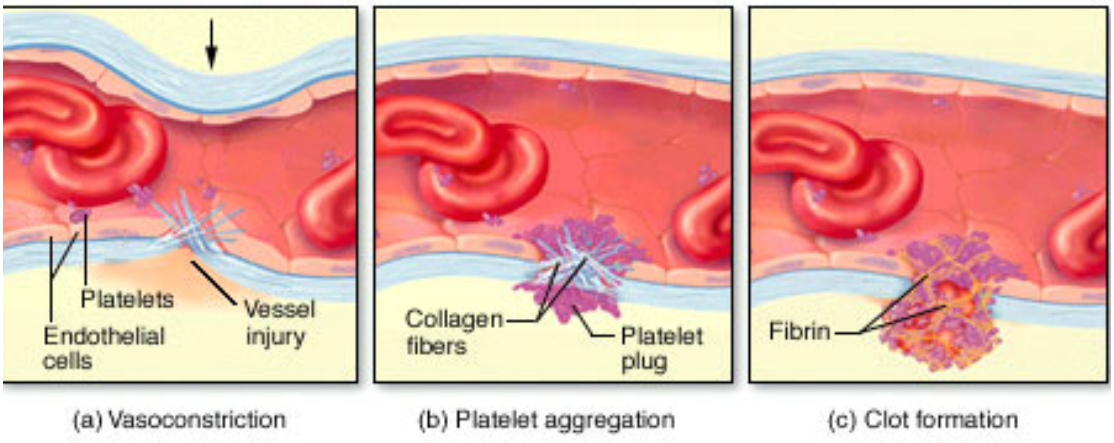

Figure 11:Primary and secondary haemostasis phases. Starting from vasoconstriction until clot formation. (**Taken from (http://intranet.tdmu.edu.ua/)**

Vasoconstriction

Vasoconstriction is the first response to the stimulation at the site of injury. The vascular wall is constricted and reduce the blood supply to the site which is considered as an early stage of clot formation.

Platelet plug

This is the second step in the clot formation. It is characterized by the platelets aggregation at the site of injury and stick together to initiate a series of activation process of forming fibrin.

Secondary haemostasis

Following the primary phase, the secondary haemostasis is characterized by the continuation of many coagulation factors and platelets aggregation in order to form the clot.

Coagulation pathways

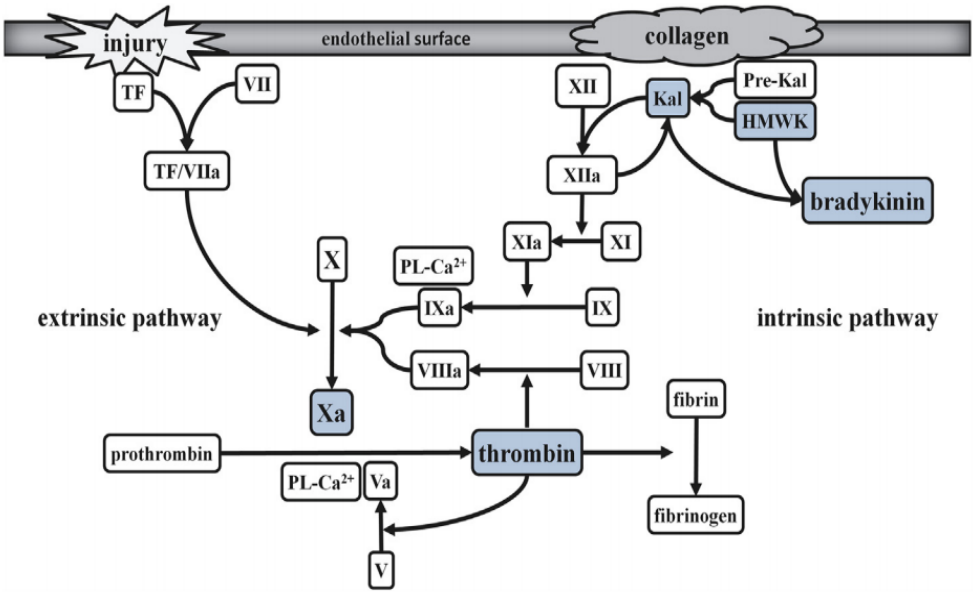

Figure 12:Coagulation pathways (intrinsic , extrinsic and common pathway) (Kraft et al. 2015).

This is classified into intrinsic and extrinsic pathways that finally lead to a common pathway resulting in the formation of fibrin (Figure 12). Firstly, the intrinsic pathway starts after contact activation between blood and the non-endothelial surface and is activated by trauma inside the vascular wall. It involves factor XII, XI, IX,VIII. Secondly, the extrinsic pathway (tissue factor) occurs following vascular wall trauma and is considered as quicker than intrinsic pathway and it involves factor VII. Finally, the common pathway combines intrinsic and extrinsic pathway in order to complete the process of clot formation. The common cascades activities of this pathway are factor I,II,V,X (Day and Taylor 2005).

2.8.3 Contact system

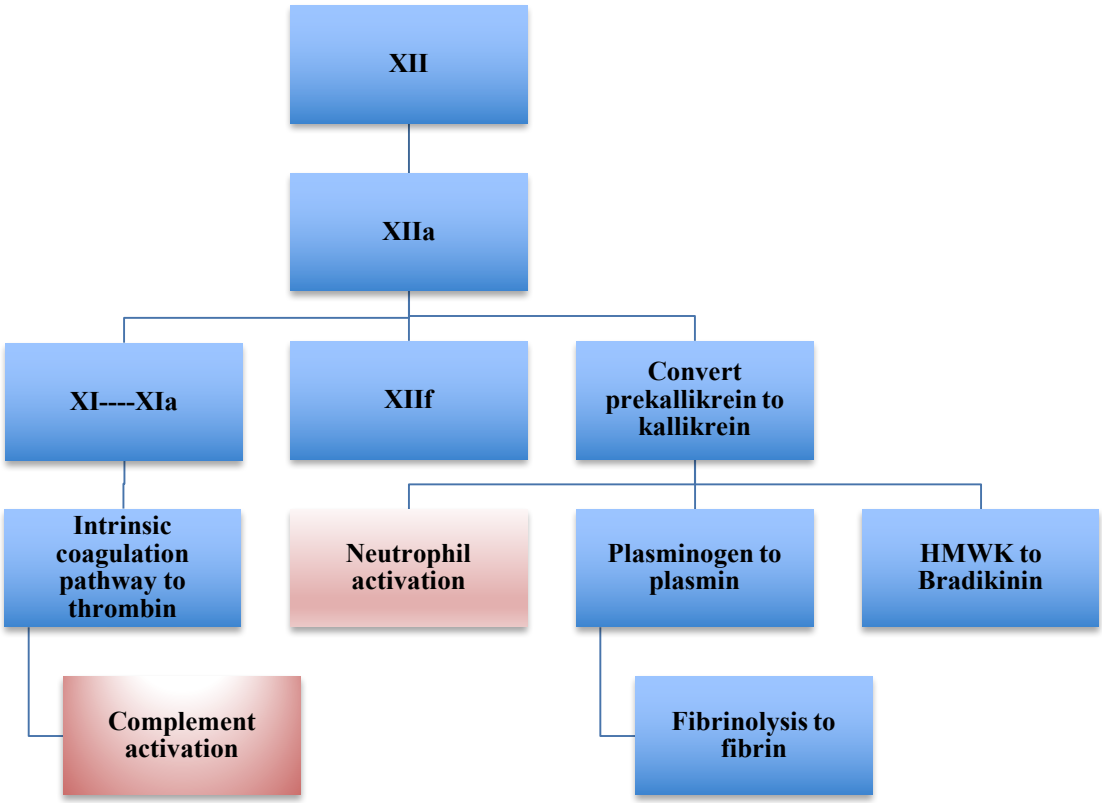

Figure 13:Contact system activation cycle.

The contact system contains four primary plasma proteins: Hagmen factor XII, XI, prekallikrein and high molecular weight kininogen (figure 13). The activation of inflammatory mediators occurs when the patient's blood comes in to contact with the non-endothelial surface (DEHP plasticised PVC tube) of CPB. The activation leads to the production of XIIa and XIIf. Factor XIIa plays a role in the initiation of the intrinsic coagulation pathway with other factors such as Hk and XI. The result from these activations is the formation of bradykinin that converts to kallikerin which is considered the initiator and a major mediator of the cellular components such as neutrophils(Lefkowitz 2008).

Factor XII (Hagmen factor)

Hageman factor is considered as an initiator of both inflammatory responses and the intrinsic pathway. The active form of factor XII converts prekallikrein to kallikrein and initiates the intrinsic coagulation cascade that leads to the formation of thrombin(Palta, Saroa, and Palta 2014).

Kallikrein –kinin system

The kininis are protein groups of serum which are synthesized in the liver. These proteins enter the blood stream as inactive state called kininogens. In addition, there are two different forms of kininogens: high molecular weight and low molecular weight.

Activation of the kallikrein

Following kallikreins activation, the tissue acts on the low molecular weight kininogens to release kallidin, that finally convert into bradykinin. This form of bradykinin attached to the receptors on the endothelial cells and secrete nitric oxide and prostacyclin which result in the releasing of the pro-inflammatory mediators.

2.8.4 Thrombin and plasmin

Activation of the coagulation pathways trigger the generation of thrombin, which results from the thrombus formation. Plasmin is an important enzyme that degrades plasma protein into fibrin. Also, it is considered as the major fibrinolytic protease (Cesarman‐Maus and Hajjar 2005).

Thrombin can initiate the immune system to release pro-inflammatory cytokines such as IL-6, TNF-α and IL-8 from the inflammatory cellular mediators monocytes, macrophages and endothelial cells. Plasmin cleaves C3 to form C3 convertase via the classical pathway.

2.8.5 Platelets and inflammation

During CPB, platelets are activated by surgical trauma, hypothermia and heparinisation (Kraft et al. 2015). Once activated, their shapes and structures differ from the normal platelets.

Platelets activation play a crucial role in the development of the inflammatory cascades via inducing the inflammatory mediators such as cytokines. It induces upregulation of P selectin and integrin family which promote the leukocytes-endothelial cells interactions (Maugeri et al. 2006).

2.9 Cytokines and chemokines

2.9.1 Chemokines

Chemokines are small proteins responsible for the migration of WBCs throughout the body. The most important chemokine is CXCL8, which is produced in response to different chemical stimuli from the inflammatory cells (neutrophils, macrophages, dendrites cells and endothelial cells). It acts in the early stage of the inflammation and works as a chemoattractant for neutrophils to the injury site (Kobayashi 2007).

2.9.2 Cytokines

Cytokines are soluble protein hormones and polypeptide that are secreted in response to stimuli. They are classified into three main groups: growth factors, lymphokines and colony stimulating factor. The source of cytokines are the inflammatory cells such as monocytes, macrophages, neutrophils and endothelial cells (Brix – Christensen 2001). Cytokines can be protective or damaging based on their concentrations, the cell type and the presence of other cytokines. In the context of cardiac surgery, the most important pro-inflammatory cytokines are IL-1, IL-6 ,IL-8 and TNF-α and anti-inflammatory cytokines IL-10 and IL-1ra (Brix – Christensen

2001). These cytokines can be measured in blood samples, and it can be detected in bronchoalveolar lavage (Brix‐Christensen et al. 1998; Kotani et al. 2000; Doughty, Kaplan, and Carcillo 1996).

Pro-inflammatory cytokines act locally to increase vascular permeability during inflammation in order to recruit leukocytes to the site of infection. These cytokines also stimulate the production of neutrophils from the bone marrow, which contribute to the infection site and enhance the healing process. Conversely, anti-inflammatory cytokines such as IL-10, IL-12 and IL-4 are secreted in order to control the inflammation and inhibit the activation of macrophages that prevents pro-inflammatory cytokines activation (Zhang and An 2007).

This is essential for immunologic and physiologic homeostasis. Some cytokines are activated directly as a result of direct contact between the blood and CPB tubing and other cytokines are activated indirectly through thrombin, kallikrein and C5a (Day and Taylor 2005; landis 2009). Increased levels of pro-inflammatory cytokines are generally associated with poor post-operative outcomes. Paparella and colleagues stated that the elevations in the pro-inflammatory cytokines (IL-6, IL-8 and TNF-α) after surgery and uncontrolled balance with anti-inflammatory cytokines (IL-10, IL-12) play a role in the development of whole body inflammation (Paparella, Yau, and Young 2002).

Cytokines and myocardial injury

Complications associated with myocardial tissue are common after cardiac surgery, and more predictable in elderly patients and patients who are re-operated(Vinten-Johansen et al. 2007; Marchant et al. 2012).

The correlation between pro-inflammatory cytokines and the changes in the myocardial functions are well known. Myocardium plays an essential role in the production of TNF-α (Sablotzki et al. 1997). Excessive release of TNF-α contributes to stimulate the secretion of other cytokines (IL-1 and IL-6) and finally to cause myocardial injury (Fahim, Halim, and Kamel 2003).In addition, excessive circulation of pro-inflammatory cytokines in the blood during CPB may lead to the development of further complications such as organ failure and severe conditions resulting in death (Bown et al. 2001).

Time course of releasing cytokines in the blood after CPB cessation

Several studies suggested that the fastest acting pro-inflammatory cytokines that appear in the blood are TNF-α and IL-1 and IL-6 (Meng et al. 2008; Brøchner and Toft 2009). They are secreted within 1 hour of CPB cessation. Peak values of these pro-inflammatory cytokines can be obtained within the period between 2 hours and 24 hours after CPB cessation. TNF-α activation reaches peak between 60-90 minutes and remains in the plasma for approximately 24 hours, whereas IL-1 reaches peak within 24 hours (Kan, Xie, and Finkel 1999; Socha et al. 2006; Meng et al. 2008), and IL-6 peak values can be detected after 1 hour and reaches peak within 6-24 hours (Royston 1997).Moreover, Giannoudis stated that IL-6 can be detected in the blood up to 5 days after the surgery(Giannoudis et al. 2008).

Pro-inflammatory cytokines

Interleukin 6 (IL-6)

IL-6 is a 26 kDa glycoprotein consisting of 184 amino acids (Wojdasiewicz, Poniatowski, and Szukiewicz 2014). It is a sensitive inflammatory marker for the early and acute phases of inflammation (Wan et al. 1996) and, considered as the first

detectable cytokine in the plasma within 60 min after the trauma and the cessation of CPB (Ferguson et al. 1997). Also, its concentration begins to increase within 2-4 hours after the operation and reaches to peak within 6-24 hours (Royston 1997). Finally, it returns to the normal levels within 3 to 5 days.

IL-6 is considered a good predictor of clinical outcomes(Donati et al. 1998). Hauser and colleagues suggested a strong correlation between the serum levels of IL-6 and mortality rate after paediatric cardiac surgery (Hauser et al. 1998). In addition, a high level of IL-6 is associated with renal and hepatic failure after surgery (Kapoor and Ramachandran 2004; Jofré et al. 2006).

Previous studies have strongly suggested that IL-6, which is upregulated early in the immune response, is a subtle indicator of the propensity for patients to illicit a heightened immune response after open-heart surgery, and indeed it is a good prognostic indicator in these patients(Giannoudis et al. 2008). Moreover, Oda and colleagues investigated the effect of sequential measurements of IL-6 in the blood for systemic inflammatory response syndrome patients(SIRS).The study showed a strong significant correlation between high levels of IL-6 (peak value) and the maximum sequential organ failure assessment score (SOFA), and IL-6 levels with the lowest platelets count (Oda et al. 2005).

Interleukin 1(IL-1)

Interleukin 1 is a form of two polypeptides (IL-1 αand IL-1β).It is secreted from different nucleated cells such as macrophages dentricitc cells, neutrophils, central nervous system microglia and endothelial cells. Also, platelets may produce IL-1 (Thomson 1992). IL-1 is a pro-inflammatory cytokine that is produced at the site of the inflammation in response to trauma other inflammatory mediators. It is an

endogenous pyrogen (fever-producing substance) due to its essential role in fever induction. It is involved in the initiation of different cascades during the acute inflammatory phase by acting as a lymphocyte activating factor, a thymocyte proliferation factor and a monocular cell factor. Abnormality levels of IL-1 may play a role in the development of systemic inflammatory response syndrome(Wajant, Pfizenmaier, and Scheurich 2003).In addition, in the acute phase of the inflammation, it is secreted in a large amount earlier than other cytokines in the blood and appear in the circulation within 1 hour (Nyström 1998).However, it's half-life is 6 minutes (Ferguson et al. 1997).

Interleukin 8 (IL-8)

IL-8 is produced by a response to the stimulation of both IL-1 and TNF-α (Tønnesen, Christensen, and Toft 1996).The production increases in the lungs following hypoxia (Kunkel et al. 1991). In addition, its level increases in the patient after surgery and is increased in patients who have septic shock(Van Devort and Danner 1990). Moreover, IL-8 post-surgery level is correlated with the duration of CPB and the occurrence of systemic inflammatory response syndrome (SIRS) (Kretzschmar et al. 1998; Rasmussen et al. 2007). IL-8 is considered as a controller of different chemoattractant activities for neutrophils and adhesion molecules phases (Ivey et al. 1995).

Tumor necrosis Factor (TNF)

TNF is a potent inducer of IL-1 in different cells. This cytokine has two species: TNF-α and TNF-β, which are produced by the activated macrophages and T lymphocytes (Bradley 2008). It plays a significant role in the regulation of systemic

inflammatory response syndrome via the control of leukocyte-endothelium interaction and the release free oxygen radicals (Jansen et al. 1990).

TNF-α reaches a peak between 60-90 min post-CPB (Kan, Xie, and Finkel 1999; Socha et al. 2006).Some reports demonstrated significant increase in TNF-α after release of cross clamping and cessation of CPB (Seghaye, Duchateau, Bruniaux, et al. 1996; Plötz et al. 1993).Nystrom reported that TNF-α is significantly higher and secreted in a large amounts in the blood within 1 hour after CPB termination (Nyström 1998). Conversely, other studies stated that TNF-α levels did not show any significant change with systemic inflammatory response syndrome patients (Finn et al. 1993; Wang et al. 1998).

C-reactive protein (CRP)

CRP is secreted from the liver as a reaction to the stimulation of different inflammatory mediators such as IL-6 (Brøchner and Toft 2009) .Clos and colleagues stated that the measurement of CRP is used to monitor the inflammatory status (Du Clos 2000).CRP is classified as an important cytokine in the prediction of inflammatory reactions with renal failure patients during the hemodialysis (Bergstrom et al. 1995). CRP normally circulates in the blood at approximately 0.8 mg/l in healthy people but in cases of acute phase stimulation, the level increases and reaches the peak within 48 hours (Pepys and Hirschfield 2003).

CRP can act as an anti-inflammatory cytokine due to its essential role in regulating PMN(polymorphonuclear neutrophils) chemotaxis (Mortensen and Zhong 2000; Zhong et al. 1998). Also, in clinical practice , it can be used as unspecific marker of infection and its plasma concentration correlates with the extended period of surgical trauma (Brix‐Christensen 2001).

Interleukin 5 (IL-5)

IL-5 is a pro-inflammatory cytokine secreted by mast cells (Plaut et al. 1989). B Cells are considered as other source of IL-5 (Paul et al. 1990). It plays a crucial role in the generation of cytotoxic T cells and eosinophils granulocyte activation during the inflammatory cycle (Zhou et al. 2010).

Interferon (IFN-γ)

Interferon is an important antiviral cytokine that plays a crucial role in regulating inflammation (Chalise et al. 2013). It is secreted by natural killer cells in response to the acute phase of inflammation. It leads to promote the natural killer activity and leukocytes migration in addition to stimulate macrophage activity(Schroder et al. 2004).

Interleukin 17A(IL-17A)

IL-17A is secreted by Th17(T helper 17) cells. It stimulates IL-6 secretion and nitric oxide.High levels of IL-17A in the blood correlates with severity of the inflammatory response (Jin and Dong 2013).

Anti-inflammatory cytokines

The human immune system is regulated by different cytokines.Anti-inflammatory cytokines may either control inflammation with pro-inflammatory cytokines or inhibit the immune system (Opal and DePalo 2000).

Interleukin 10 (IL-10)

IL-10 is a cardioprotective cytokine acting as a suppressor to the immunological activities in the blood to maintain equilibrium status.IL-10 is produced from different cells such as TH2(T helper 2) lymphocytes,monocytes and neoplastic B cells (Jorens et al. 1992). It is a regulator cytokine in the blood which stimulates the secretion of

the IL-1 receptor antagonist (IL1-ra) and suppresses both IL-8 and IL-6 (Gastl et al. 1993).IL-10 plays a fundamental role in the diagnosis of systemic inflammatory response syndrome (SIRS) and sepsis patients. Montz study suggested that IL-10 level is correlated with the severity of disease (Montz et al. 1994). IL-10 showed a significant effect in the inhibition of TNF-α and nitric oxide, and this inhibition also suppressed neutrophils accumulation (Yang, Zingarelli, and Szabó 2000). Moreover, a study conducted by Rodriquez- Gasper showed a strong association between IL-10 as anti-inflammatory cytokine with TNF-α of patients who have fatal and worse outcomes (Rodríguez-Gaspar et al. 2001).

Interleukin- 1ra (IL-1ra)

IL-1ra is produced by monocytes and macrophages. It acts to block the functions of both IL-1 α and IL-1 β by competitive inhibitor at the IL-1 receptor (Opal and DePalo 2000). In the context of CPB, IL-1ra plays a pivotal role in the controlling of the balance situation between pro-inflammatory and anti-inflammatory cytokines(McBride et al. 1995). In addition, Sikora's study on 37 burned children showed a significant association between IL-ra levels and the prognosis of systemic inflammatory response syndrome(Sikora et al. 2008).

Interleukin 4 (IL-4)

IL-4 is a pleiotropic cytokine (cytokine that affects the activity of other cell types) which leads to the activation of T helper cell differentiation (T helper is an immune cell plays a role in the adaptive immune system). It is a protein secreted from the mast cells and T helper cells, and its most important function is to block and inhibit the release of pro-inflammatory cytokines such as IL1, TNF-α IL-6,IL-8 and macrophage inflammatory protein (MIP)(Opal and DePalo 2000).

Interleukin12 (IL-12)

IL-12 is anti-inflammatory immunoregulatory cytokine produced by antigen presenting cells (Chehimi and Trinchieri 1994; Beadling and Slifka 2006). Historically, IL-12 was identified as a product of a specific virus called Epstein barr virus and also was known as natural killer cell stimulatory factor (Horiuchi et al. 1999), it plays a crucial role in the regulating and managing the innate inflammatory responses at the site of injury by inhibition of inflammatory cascades and pro-inflammatory mediators (Hamza, Barnett, and Li 2010). Recently, IL-12 has expanded to include many cytokine members working under the same umbrella of IL-12. These cytokines are IL-23, IL-27, IL-35, and they all lead to innate development of Th1 cells(Brombacher, Kastelein, and Alber 2003; Beadling and Slifka 2006)

Interleukin 13 (IL-13)

IL-13 is a potent modulator for human monocytes and B cells which is secreted by the stimulation of T lymphocytes. It is produced in order to suppress and regulate the production of TNF, IL-1, and IL-8. It is also suppresses the inflammatory injury of the lung(Lentsch et al. 1999).

Interleukin11(IL-11)

IL-11 is 178 amino acid peptide cytokine secreted by different cells such as osteoblasts, fibroblasts and chondrocytes (Putoczki and Ernst 2010).This protein plays a crucial role in many cellular activities such as regulating macrophages differentiation, binding of antigen antibodies, the inhibition of lipoproteins lipase induces synthesis of the acute phase of protein and performing anti-inflammatory response during the inflammatory pathways(Dinarello 1999). It is rarely detected in

the healthy subjects' serum(Schwertschlag et al. 1999),whereas it can be detected in patient who are developing inflammation and cancers(Zheng et al. 2001; Hanavadi et al. 2006).

2.10 Anti-inflammatory strategies to attenuate the inflammatory response

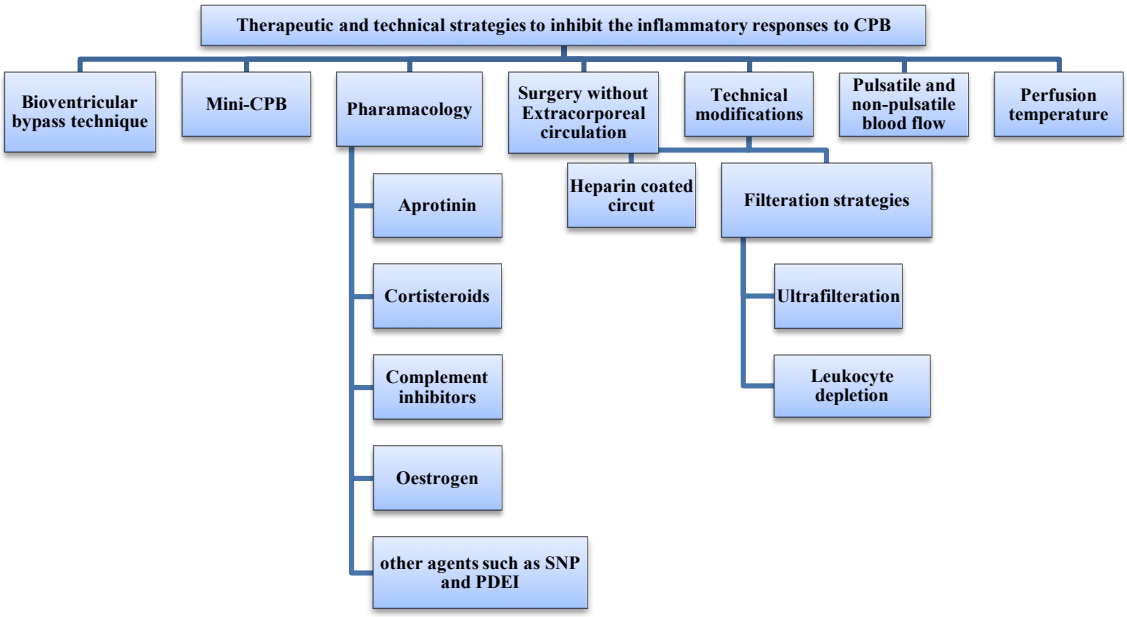

Figure 14:Anti-inflammatory strategies to attenuate inflammatory response to CPB.

Several therapeutic strategies have been used over the past 50 years to attenuate the poor outcomes that may result from using CPB. Current strategies are aimed to maintain a safe environment and less complications after the surgery (Figure 14).

Mechanical and technical modifications to CPB system include: hemofiltration, circuit miniaturization to reduce the priming volume and area of blood /tube contact, leukocyte filtration and heparin coated circuits.

In terms of the therapeutic agents, cortisteroids have been used for many years to attenuate the inflammatory response. Charette and colleagues demonstrated that the administration of steroids lead to the inhibition of inflammatory cells gene

transcription (Charette et al. 2008). In addition, aprotinin (Trasylol) is an effective drug that is used in most cardiac operations (Jansen et al. 1996).

Other potential pharmacological inhibitors include: complement inhibitors, antioxidants, phosphodiesterase inhibitors and NO donors (sodium nitroprusside). These techniques and therapeutic agents will be explained in details in the following sections.

2.10.1 Cantharidin blister model

Acute inflammatory response can be assessed by in vitro and in vivo methods. Several in vivo methods were developed in the last 20 years. These include systemic inflammatory reaction after endotoxin inhalation(Michel et al. 1997),negative pressure induced by a skin blister model(Follin 1999) and finally the novel cantharidin blister model (Day et al. 2001).The cantharidin technique is considered a quick and non-invasive technology that provides access to cells under the skin to investigate leukocytes trafficking and cytokines production at the site of injury.

The technique can be maintained for several days in order to characterize the innate of inflammatory responses (figure 15).

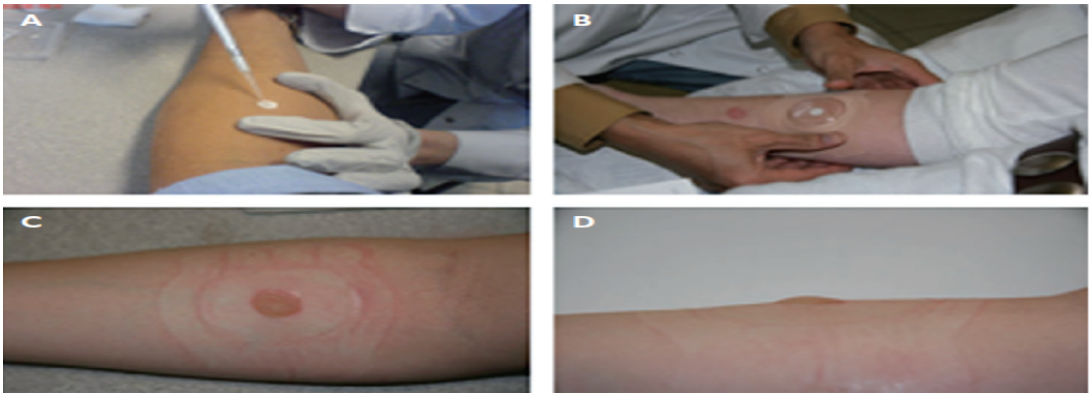

Figure 15:Cantharidin induced blister.(A) Placing a filter paper disc on the foream after adding 25µl of 0.1% cantharidin solution to the disc.(B) Cover the disc.(C) by 24 h there is a significant inflammation.(D) Blister shape(Dinh et al. 2011).

2.10.2 Biventricular bypass technique (Drew-Anderson technique)

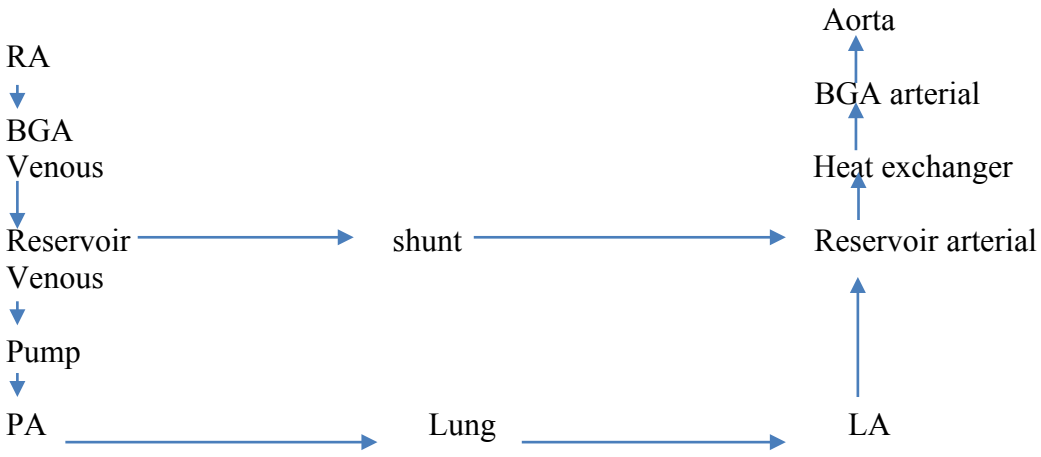

Figure 16:Drew-Anderson technique.(LA =Left atrium, PA= pulmonary artery, RA: right atrium, BGA=Blood-gas analysis. the concept is based on purifying the blood during the surgery in patient's own lung). Adopted from (Richter et al.2000).

The Drew-Anderson technique is a promising technology in the majority of cardiac operations particularly for high risk patients (Paparella, Yau, and Young 2002).The technique is based on using the patient's own lung instead of the oxygenators which may enhance the pulmonary functions over the surgery (figure 16). Several clinical and animal studies reported the benefits of Drew-Anderson technique. A study conducted by Mendler on dogs showed a significant improvement in the lung functions (Mendler, Heimisch, and Schad 2000). Richter and colleagues studied the effect of using Drew-Anderson technique on 30 patients. They reported the significant reduction in the circulating pro-inflammatory cytokines (IL-6 and IL-8), and increasing in IL-10 levels (Richter et al. 2000).

2.10.3 Mini-CPB techniques

Several manufacturers developed mini-cardiopulmonary bypass systems to reduce the implications of conventional CPB. These new small systems consist of: closed circuit, centrifuge pump, hollow fibre membrane oxygenators, suction and reduced

amount of membrane surfaces.The biocompatibility and the new design of mini-CPB (not including venous reservoir, the reservoir is the patients and entering air into the venous cannula is avoided) reduces thrombin formation and limits the development of poor complications after the surgery (Baikoussis, Papakonstantinou, and Apostolakis 2014).Moreover, reducing the circuit size leads to a significant reduction in the hemodilution (Hickey et al. 2006).

Minimized extracorporeal circuit (MECC)

Minimized extracorporeal circuit is a promising technology in cardiac surgery. The results from many operations showed a significant reduction in the morbidity rates and lowers pre-operative mortality(Anastasiadis et al. 2013).

MECC consists of a shorter PVC tube in length (80-150 cm), a centrifugal pump and membrane oxygenators. A minimized circuit aims to reduce the priming volume and the contact area between the blood and PVC tube (figure 17). The major differences between CCPB and MECC are shown in below table (table 1).

Conventional CPB(CCPB)	Minimized Extracorporeal circuit(MECC)
PVC tube length is 160 cm-300 cm	PVC tube length is 80-150 cm
Prime volume 1700-2200 ml	Prime volume 450-500 ml
Platelets activation is lower due to the tube length	Platelets activation is higher due it the shorter tube length
Roller pump increase the zones of stagnant blood flow	Centrifugal pump reduces the stagnant blood flow
Blood reservoir increase the blood volume and increase the risk of triggering inflammatory cascades	No blood reservoir

Table 1:Differences between CPB and MECC. (Curtis, Vohra, and Ohri 2010).

Interestingly, MECC lead to greater improvements in the post-operative outcomes compared to CCPB(Anastasiadis et al. 2013). In terms of the mortality rates, there is no significant difference between the MECC and CCPB (Remadi et al. 2004; Stalder

et al. 2006). However, the cytokines concentrations such as CRP, IL-6 and TNF-α are lower with MECC than CCPB (Wippermann et al. 2005).

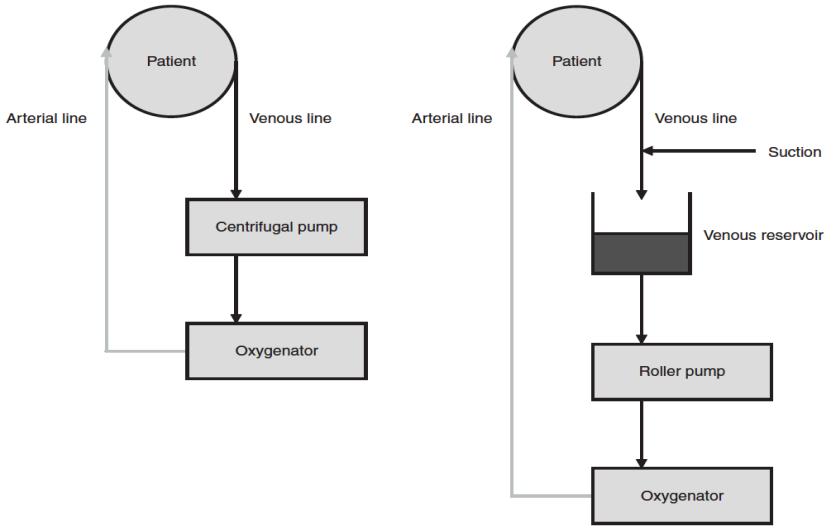

Figure 17:Schematic of the miniaturized extracorporeal circuit (MECC) on the left and conventional extracorporeal circulation (CECC) on the right (Vohra et al. 2010).

Minimal invasive extracorporeal circulation (MiECC)

MiECC is an extracorporeal life support system used to perform coronary artery bypass graft procedures (Wiesenack et al. 2004). It consists of the same components of the mini-CPB which are biological inert contact surface, reduced prime volume, centrifugal pump, heat exchanger, membrane oxygenators, cardioplegia system, venous bubble trap, venous air removal and shed blood system (Anastasiadis et al. 2016).

Several studies have investigated the impact of the inflammatory responses with conventional cardiopulmonary bypass compared to the MiECC system. MiECC showed a significant reduction in the severity of systemic inflammatory response syndrome (Anastasiadis et al. 2016).This may be due to its coating and smaller circuit size that limits the initiation of inflammatory mediators in the blood.

MiECC deployment showed a strong association with IL-6 significant reduction after the surgery(Fromes et al. 2002; Immer et al. 2007; Liebold et al. 2002) and lower peak values of neutrophils elastate (a marker of the neutrophils activation) (Fromes et al. 2002; Abdel-Rahman et al. 2005; Ohata et al. 2007). A recent meta study on 24 studies stated that MiECC leads to decrease the mortality rate significantly rather than conventional cardiopulmonary bypass system (Anastasiadis et al. 2013).

Resting heart system (RHS)

RHS is an integrated, closed loop system with low prime volume (600 ml) offering a minimum contact between blood and artificial surfaces of the circuit, with the rationale that it would lead to reduction of further complications post-surgery (figure 18). The system has a unique feature which is a detector that can detect smaller bubbles in the circuit (Benedetto et al. 2009).

A study conducted Kamiya and colleagues suggested that using resting heart system leads to decrease number of leukocytes in the blood after the operation and significantly reduced CRP levels after 72 hours (Kamiya et al. 2006).

Figure 18:Medtronic Resting heart system(Anastasiadis, Antonitsis, and Argiriadou 2012).

2.10.4 Technique modifications for CPB

Heparin coated circuit (HCC)

It has been established that the contact between the blood and non-physiological surface layer (PVC tube) during CPB is a mechanism that initiates the inflammatory response (landis 2010). Coating the CPB surface with biocompatible materials showed a significant improvement in the clinical profile. Several materials have been coated to the CPB tube including heparin, synthetic proteins and phosphorylcholine. However, heparin is the most widely coated material used which mimics the endothelial surface that contain heparin sulfate (Apostolakis et al. 2010).

Heparin has an anti-inflammatory role (Tyrrell et al. 1998). Nelson and coworkers stated that heparin can inhibit the adhesion molecules via blocking the activity of P and L selectins (Nelson et al. 1993). IL-6 and IL-10 levels were significantly reduced with heparin coated circuit (Giomarelli et al. 2000).

Commercially, there are two heparin coated methods: firstly, the Duraflo II heparin coated circuit from Baxter company, which uses ionic bonded unfractioned heparin. This reduces complement activation but is not efficient in inhibiting the coagulation pathways. Secondly, the Carmeda bioactive system from Medtronic which is based on the end attached bonded heparin and considered a more efficient method than Duraflo in terms of the regulation of both complement and coagulation cascades (Lundblad, Moen, and Fosse 1997; Baufreton et al. 1998).

Perfusion Temperature

It is well established that inflammatory mediators are affected by the temperature (Birdi et al. 1999). Normothermic CPB increases the release of cytokines, cellular

and soluble mediators of inflammation, whereas hypothermia reduces the production and release of these mediators during the operation(Fairchild et al. 2000).

Pulsatile and non-pulsatile blood flow

Several studies reported the importance of pulsatile flow rather than non-pulsatile flow in terms of decreasing adhesion molecules and attenuating inflammatory responses after the termination of CPB(Haines et al. 2009; Sievert and Sistino 2012). The key behind this is the improvement of microcirculation and diffusion between cells (Poswal et al., 2004). Neil and colleagues measured the microcirculation levels for 20 patients who were admitted to London Health Sciences Centre between August 2008 and April 2010 for CABG surgery. The results suggested that pulsatile flow is better than non-pulsatile flow in terms of attenuating the inflammatory responses (O'Neil et al. 2012).

Filtration techniques

Ultrafiltration

CPB deployment leads to hemodilution (Warren, Watret, et al. 2009). Hemodilution is triggered by the excessive accumulation of fluids and the body water after CPB termination, which is caused by the returning of diluted blood back to the patient.

Hemodilution can be reduced by using ultrafiltration techniques. In north America, around 75% of cardiac operations deploy ultrafiltration techniques (Groom et al. 2005). There are three integrated ultrafiltration techniques with CPB, which are: conventional ultrafiltration technique (CUF), modified ultrafiltration filtration technique (MUF) and zero-balance ultrafiltration(Wang, Palanzo, and Ündar 2012). These techniques are widely different but they have the same benefits in the removing of the excess free water and inflammatory mediators such as pro-

inflammatory cytokines (IL-6, TNF-α ,IL-8) and complement cascades (Mahmoud et al. 2005).

Conventional ultrafiltration techniques (CUF) are commonly used for paediatric CPB operations to maintain moderate hemodilution. The inlet line of this filter is connected to the arterial line and the outlet to the venous reservoir. The filtration process is started after the rewarming phase of bypass (Maluf 2003).This technique showed a significant impact in the reduction of circulatory inflammatory cytokines and reduced need for blood transfusions (Journois et al. 1996). Additionally, many clinical benefits were reported such as improving cardiovascular performance(Bog'a et al. 2000)and increasing the haematocrit (Kiziltepe et al. 2001).

Modified ultrafiltration technique (MUF) was developed by Naik and colleagues (Naik, Knight, and Elliott 1991). This filtration process is deployed after CPB termination. The filter is positioned in the bypass circuit. The inlet line is placed close to the arterial cannula and the outlet line is kept free in a sterile tube to be inserted into the right atrium. MUF filter is considered as a safe and reliable technology which achieves hemoconcentration, lower blood loss and significant reduction in post-operative bleeding (Torina et al. 2010; Pérez-Vela et al. 2008). Kiziltepe and colleagues found that the combination between CUF and MUF is effective and more safe for adult patients (Kiziltepe et al. 2001).

A third ultrafiltration method is called zero-balance which is similar to the conventional ultrafiltration. It is usually performed after rewarming phase (Wang, Palanzo, and Ündar 2012). A clinical study conducted by Tallman and coworkers demonstrated the efficacy of zero-balance ultrafiltration during CPB in the removal of inflammatory mediators (Tallman, Dumond, and Brown 2002).

Leukocyte depletion

The first leukocyte depletion filter was created by Pall company (LG6B; Pall Biomedical Products, East Hills, NY) in 1991(Boodram and Evans 2008). State-of the art leukocyte depletion filters are classified into four groups: leukocyte filters in the arterial line, leukocyte filters in the venous line, leukocyte filtration of blood cardioplegia and leukocyte filters of the suction blood (Matheis et al. 2001). These filters aim to protect heart and lung from any damage via the attenuation of neutrophil activation and inflammatory cytokines (Di Salvo et al. 1996; Gu, Boonstra, and van Oeveren 1996; Gu, De Vries, et al. 1999).

A series of animal and human studies were conducted to determine the significant effect of leukocyte depletion filter in the improvement of post-operative outcomes.

Animal models have shown significant beneficial outcomes from using leukocyte depletion filters. A comparison study was performed between isolated rabbit heart in order to assess a leukocyte depletion filter efficacy in reperfusion rates and reduction of inflammatory mediators in the blood. The first group was perfused with whole blood while the second group was perfused with the leukocyte depletion filter. The results showed higher recovery rates in the second group and better outcomes in terms of the removal of pro-inflammatory cytokines and other mediators (Sawa et al. 1994). In addition, in pigs, the technique showed a significant reduction in ischemia injury when it was deployed before cardioplegia arrest (Lazar et al. 1995).

From the clinical point of view, studies evaluated the leukocyte depletion filter to investigate its performance during CPB in terms of reducing the circulating inflammatory cytokines and the morbidity rate. It was reported by Sawa and colleagues that leukocyte depletion filter attenuate reperfusion injury during cardiac

surgery (Sawa and Matsuda 2001). Another study was conducted on 32 patients undergoing elective cardiac surgery, and confirmed the noteworthy effect of leukocytes depletion filter in the reduction of IL-8, P selectin and ICAM-1(Chen et al. 2004).

Leukocyte depletion filter appears to improve post-operative respiratory outcomes after CPB, particularly with patients who have low pre-operative oxygenation before the surgery (Morioka et al. 1996; Sheppard, Gibbs, and Smith 2004; Johnson et al. 1995).This improvement reduces the ventilation time and the intensive tension unit length of stay (Ohto, Yamamoto, and Nakajima 2000).

2.10.5 Surgery without extracorporeal circulation

Off pump coronary artery bypass (OPCAB)

OPCAB has been used in cardiac surgery since 1964 (Kolessov 1967). Operating while the heart is beating is the safest approach to avoid post-operative complications and unwanted implications (Uyar et al. 2014). There is no contact between blood and non-endothelial surface tubes and the degree of ischemia and reperfusion are less than CPB. The trigger of inflammatory cascades and production of pro-inflammatory cytokines are less than other surgical approaches (Rasmussen et al. 2007).

A series of clinical studies were focused on measuring the difference between using CABG surgery with or without CPB. Patients who underwent OPCAB had less circulating TNF-α and IL-8 with less production and activation of other inflammatory mediators (Asimakopoulos 2001; Biglioli et al. 2003).

Avoiding CPB improves the post-operative outcomes. IL-6 levels remain consistent in patients with and without CPB and other inflammatory mediators such as the complement system(Tarnok et al. 1999; Gu, Mariani, et al. 1999).These findings

suggest that modulating the inflammatory response during cardiac operations is possible with or without CPB deployment.

Despite the benefits of using OPCAB, there are also some disadvantages in using this technique, such as:

1. The connection of the graft to the coronary artery is more difficult due to movement of the heart.

2. A myocardial stabilization device must be used with the off pump.

3. The surgeon may have to perform many bypass grafts due to the heart moving (Peter and Suyker 2002).

Minimally invasive cardiac surgery (MIDCAB)

Minimally invasive cardiac surgery techniques have been introduced into the cardiac surgery field over the last few decades which have been shown to decrease pain and surgical trauma(Walther et al. 1999).Performing surgery without opening the sternum or the chest contributes to minimizing inflammatory responses. Incisions can be made using central aortic cannulation or peripheral cannulation via the femoral or axillary artery, although the disadvantage of an incision via the femoral artery is an increased risk of stroke (Gammie et al. 2010).

As seen in figure 19, MIDCAB does not require opening the sternum and placing 10-12 incisions at the end of the operation. It requires a small incision between the ribs with 3-5 incisions. This technique has many advantages such as shorter time of recovery and hospital stay, few complications and implications after operation, less bleeding and low risk of infection(Iribarne et al. 2011).

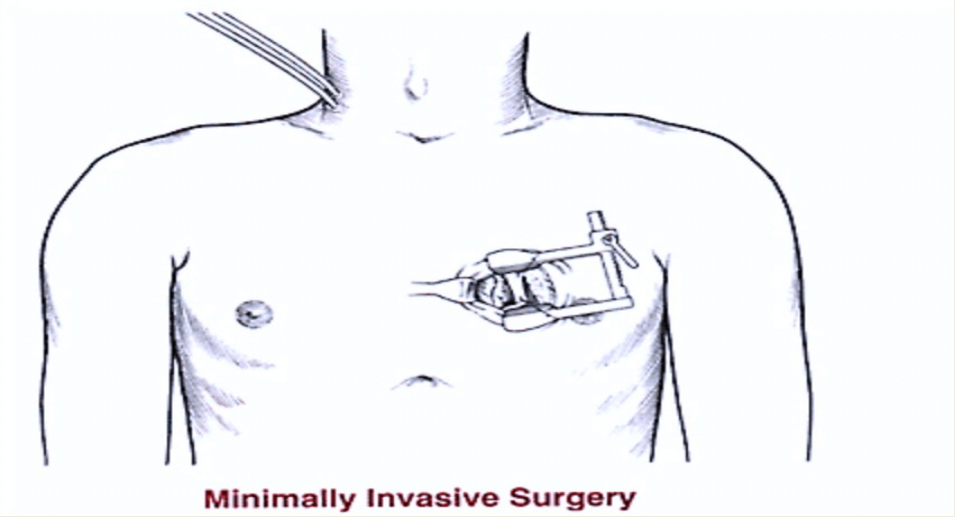

Figure 19:Minimally invasive incision.(**Taken from (http://www.cts.usc.edu/hpg-midcab.html).**

Multivessel grafting

Multivessel grafting is an approach used during off-pump technology. This involves an incision through the sternum that allows surgeons access to all vessels. Several studies stated its efficacy in the elimination of developing inflammatory response during the surgery (Benetti et al. 1991; Buffolo et al. 1996).

2.10.6 Pharmacological agents

Aprotinin

Aprotinin (trade name trasylol) is defined as a nonspecific serine inhibitor (bovine version of the small protein basic pancreatic trypsin inhibitor). For more than 30 years, surgeons have used aprotinin as an anti-fibrinlytic agent in cardiac surgery due to its role in stopping bleeding and inhibiting inflammatory responses by regulating both cellular and humoral inflammatory cascades that lead to SIRS (Royston 1996; Englberger et al. 2002; Hill et al. 1995).

In terms of the suppressing activities of aprotinin,it can decrease concentrations of both IL-6 and IL-10 after the cardiac operation(Tassani et al. 2000).Also, the cellular

interaction activation between neutrophils and endothelial cells are decreased (Asimakopoulos et al. 2000).Aprotinin suppresses the production of IL-8 during CPB and reduces both neutrophils accumulation and adhesion molecules(Hill, Whitten, and Landers 1997). In terms of drug dosage,it has been reported that a full dose of aprotinin contributes to improving the anti-inflammatory responses after CPB termination(Brown et al. 2009). This response is characterized by activating the anti-inflammatory cytokines specifically IL-10.

Despite all of the above advantages of aprotinin, there are some arguments regarding the deleterious outcomes from the excessive using of aprotinin such as blocking of blood vessels, stroke, renal failure and saphenous vein graft closure(Mangano, Tudor, and Dietzel 2006).

Corticosteroids

Corticosteroids have long been used in cardiac surgery to suppress the impact of inflammation associated with cardiac surgery (Paparella, Yau, and Young 2002). The well-known corticosteroids used in the clinical and surgical field are methylprednisolone and dexamethasone. Basically, steroids can inhibit the phospholipase activation and lead to improve myocardial function (Engelman et al. 1989).They act to reduce the damaging effect of pulmonary and myocardial activities after the termination of CPB (Wan, LeClerc, and Vincent 1997).

Glucocortisteroids can suppress inflammatory cascades specifically, in the cases of chronic inflammation (Coutinho and Chapman 2011).The suppression is achieved by activating anti-inflammatory genes and inhibiting the pro-inflammatory cytokines in the blood (Barnes 2011).Administration of glucocortisteroids prior to the surgery suppresses the complement activation system and attenuates the production of the

common pro-inflammatory cytokines such as TNF-α, IL-6 and IL-8(Andersen et al. 1989).Furthermore, methylprednisolone before the surgery produces a significant reduction in the IL-6 and IL8 levels (Kawamura et al. 1995).

Several studies have found that steroid administration during OHS with CPB reduces inflammatory responses via inhibition the humoral and cellular cascades (Kozik and Tweddell 2006; Levy et al. 1998).This improves patient post-operative outcomes and reduces ITU length of stay (Yilmaz et al. 1999). Wan and colleagues stated that the best time of steroid administration is prior to the surgery (Wan et al. 1996)

Complement inhibitors

The central role of the complement system in the acute inflammatory response to CPB provides sufficient rationale for its inhibition.The anaphylatoxins and C5b-9 are direct mediators of the inflammatory response, and C5a is the principal agonist for activating neutrophils, and is a potent chemoattractant for neutrophils, monocytes, macrophages, eosinophils, basophils, and microglial cells.

During cardiac surgery, the complement system induces the release of cytokines and chemokines leading to damage to tissues and organ dysfunction.The severity of post-operative outcomes is correlated with the activation levels of the complement system(Amara et al. 2008).Hence, the demand for complement inhibitors increased over many decades. Researchers and pharmaceutical manufacturers developed multiple types of inhibitors that can lead to blockages of complement system activation during surgery. Some examples of the most common inhibitors are shown in table 2.

Complement inhibitor	Mechanism of action
Complement activation blocker -2 (CAB-2)	Inhibit C3 and C5 convertase
Soluble complement	Inhibit C3 and C5 convertase
Factor D antibody	Inhibit alternative pathway
Properdin antibody	Inhibit stabilization of C3
C5 antibody	Inhibit C5 activation
Compstatin	Inhibit C3 activation

Table 2:Complement inhibitors(Franco and Verrier 2003).

Oestrogen

Oestrogen are a group of steroid hormones that play a crucial role in maturation development and maintenance of female characteristics. Women have significantly lower rates of mortality and infection compared to men (Oksuzyan et al. 2008). This rate slightly changes in case of inflammatory response during CPB (Straub 2007). Dulos and colleagues introduced oestrogen in rats and investigated its ability to suppress the inflammatory response. The results showed a significant decrease in the circulating pro-inflammatory cytokines such as TNF- α (Dulos et al. 2010).

Phosphodiestrase inhibitors (PDEI)

Phosphodiestrase inhibitors are therapeutic agents with an anti-inflammatory action. PDEIs include amrinone, milrinone and pentoxyfylline. All those inhibitors play a crucial role in the suppression of inflammatory mediators, pro-inflammatory cytokines in the blood and the cellular activation such as adhesion molecules (Banner et al. 1996).

Numbers of studies have demonstrated the effect of all PDE inhibitors in the cytokines levels. Takeuchi and colleagues introduced amrinone to a group of rabbits to determine its role in the controlling of TNF-α and IL-1 levels. They reported a significant suppression of these cytokines (Takeuchi et al. 1999). Another animal study on mice by Nemeth proven the inhibition effect of this drug on the of IL-6 and IL-10 concentrations (Németh et al. 1997).

Milrinone is another agent that inhibits the action of inflammatory cytokines. It is characterized by the elevating of adenosine levels in the blood.It has been recommended to administer this agent before CPB in order to achieve a successful inhibition of the cytokines (Hayashida et al. 1999).

Pentoxifylline is a non-specific inhibitor with anti-inflammatory effects.It has an attenuation effect on the neutrophils elastase, C- reactive protein and inflammatory cytokines(IL-6, IL-8 and IL-10) in elderly people who are undergoing CPB (Boldt et al. 2011).This inhibitor plays a key role in the attenuation of many inflammatory activities and inflammatory cytokines such as TNF-α, neutrophils activation with endothelium and decreases the release of endotoxins.

Sodium nitroprusside (SNP)

As stated earlier, pro-inflammatory cytokines and endotoxins promote inducible nitric oxide (iNO) production. The administration of NO suppresses the activation of pro-inflammatory cytokines which result in the inhibition of iNO (Kessler et al. 1997).

SNP is NO donor. It is a potent and effective anti-inflammatory therapeutic agent. It was discovered in 1850, and the its first therapeutic use was reported in 1951(Drover et al. 2015). It plays a key role in the suppression of hypertension and inflammatory mediators. Several studies elucidate its significant impact in the inflammatory response with the use of CPB. Seghaye and colleagues administered SNP on 16 children undergoing CPB, and the results showed a significant reduction in the complement activation(Seghaye, Duchateau, Grabitz, et al. 1996). A study conducted by Massoudy and colleagues confirmed the inhibitory effect of SNP in the IL-6 and IL-8 concentrations (Massoudy et al. 1999).Also, in clinical profile, the

administration of SNP during CPB leads to a significant reduction in neutrophil accumulation, complement system components and the number of white blood cells (Massoudy et al. 2000).

Anti- cytokine monoclonal antibodies

Monoclonal antibodies are the newest agent introduced into cardiac surgery in order to attenuate the deleterious effects of inflammatory responses after the surgery (Dybdahl et al. 2002). This agent is developed in order to suppress the activity of the common inflammatory cytokines (TNF-α, IL-1 and IL-8)(Waykole et al. 2009).

In the context of cardiac surgery, the administration of this agent during open heart surgery showed a significant reduction in the pro-inflammatory cytokines. A study conducted by Gurevitch and colleagues investigated the effect of monoclonal TNF- α on rats.The results showed a significant reduction in TNF- α levels, and improved post-clinical outcomes (Gurevitch et al. 1997).

Free radical scavengers and antioxidants

Reactive oxygen species such as hydrogen peroxide and hydroxyl radicals are generated in the blood upon reperfusion following CPB surgery. It plays an essential role in tissue injury(Barta et al. 1990). Raja and colleagues demonstrated the importance of free radical scavengers such as enzymatic scavengers and antioxidants in the control of inflammatory responses after CPB (Shahzad G Raja 2005).

High dose Vitamin C and Vitamin E

Vitamin C and vitamin E are antioxidants agents given to the patient prior to cardiac surgery. A high dose of vitamin C decreases the cell membrane's lipid peroxidation, improves the hemodynamics and reduces length of hospital stay following surgery (Dingchao et al. 1994; Barta et al. 1990).Vitamin E reduces the plasma concentration

of hydrogen peroxide and decreases cells' membrane lipid peroxidation which result in the inhibition of inflammatory mediators (Cavarocchi et al. 1986; Barta et al. 1990).

Mannitol

Mannitol is a hexhydric alcohol related to the mannose group. Due to its physicochemical characterizations, it causes a fluid shift from the intracellular side to the extracellular side, causing to dehydration of the tissue (Cavone et al. 2012). In the clinical context, mannitol plays an essential role in the management of inflammatory mediators during cardiac surgery. Ziegeler and colleagues evaluated the ability of mannitol to modulate immunosuppression after CPB. They administered mannitol on forty-five patients and the results showed a significant suppression of the inflammatory cascades (Ziegeler et al. 2009).

Cyclooxygenase inhibitors

Aspirin is a non-steroidal anti-inflammatory drug (NSAID) used in the majority of cardiac operations as a pain killer and antiplatelet activator. The common version of the non-steroidal anti-inflammatory drug is called indomethacin. This traditional drug inhibits two types of cyclooxygenase (COX-1 and COX-2).A group of nonspecific COX inhibitors increase the pulmonary vascular resistance and acute lung dysfunction with CPB(Cave et al. 1993; Shafique et al. 1993).

Studies have demonstrated its direct effect in decreasing post-operative fever and chest pain after CPB termination (Heindl and Becker 2001; Möbert and Becker 1998) .

N-Acetylcysteline

A high dose of N-Acetylcysteline inhibitor before or during CPB reduces the activation of both neutrophils and pro-inflammatory cytokines. N-Acetylcysteline improved the oxygenation and did not produce any negatively impact of the acute respiratory distress syndrome (Shahzad G Raja 2005).

2.11 CPB's post-operative complications

2.11.1 Postcardiotomy syndromes

Postcardiotomy syndrome is an autoimmune response against damaged cardiac tissue. The first description was in 1953 for a patient having a closed mitral commissurotomy (Soloff et al. 1953). Three years later, surgeons realized that the syndrome can result from the valvetomy and can be treated by cortisone. Then, it was recognized that the trauma was a part of the syndrome and the reactivation of the fever was not the cause of the syndrome (Larson 1957; Lisan, Reale, and Lokoff 1959).

Postcardiotomy is developed within a week to six weeks after the surgery and characterized by high fever, chest pain and dyspnoea(difficulty breathing)(Scarfone, Donoghue, and Alessandrini 2003).The standard treatment for postcardiotomy syndrome is the administration of non-steroidal anti-inflammatory drugs that lead to inhibition of disease progression of the diseases (Eguchi et al. 2010).

2.11.2 Acute respiratory distress syndrome (ARDS)

Acute respiratory distress syndrome (ARDS) is defined as a medical condition where patients have excess fluid in the alveoli in conjunction with widespread inflammation in the lung. The first description of ARDS was introduced by Ashbaugh and

colleagues in 1967(Ashbaugh et al. 1967). The syndrome is characterized by severe hypoxia and stiff lungs (Ware and Matthay 2000).

ARDS involves two major mechanisms that injure the lung; firstly, alveolar damage and secondly;pulmonary epithelial and cellular damage that is characterized by series of inflammatory cascades (Fanelli et al. 2013). In the context of CPB, this syndrome occurs in 0.5-1.7% of patients and can associated with the multi-organ failure and death in 50-92% of patients (Asimakopoulos et al. 1999). Clinically, to treat ARDS patients, they are connected to mechanical ventilation. The future trend of the ARDS treatment will focus on the development of therapeutic agents based on the gene description and the mesenchymal stem cell.

2.11.3 Systemic inflammatory response syndrome (SIRS)

Systemic inflammatory response syndrome (SIRS) is a non-specific inflammatory state affecting the whole body defined as a complex related to systemic inflammation, organ dysfunction and organ failure. This insult may be infection, trauma, burn or other injury. In the United States, it is reported that SIRS is a leading cause of mortality and morbidity. More than 400,000 patients develop SIRS every year and approximately 100,000 of those patients die (Levy et al. 1998). SIRS may also lead to further consequences such as sepsis (new definition of SIRS which is separate from sepsis as SIRS overly–sensitive and nearly all (over 90%) of patients admitted to ITU met SIRS criteria) and multiple organ failure (figure 20) (Shankar-Hari et al. 2016).Clinical criteria allow clinicians to identify SIRS patients.The American College of Chest/Physicians / Society of Critical Care Medicine defined four criteria to determine SIRS in patients. These are: temperature of >38°C or <36°C; heart rate >90 beat per minute; respiratory rate >20 breath per minute; and

WBC >12000 mm^3 or <4000 mm^3) or >10% immature band). If two of these four factors met together, the patient is classified as having SIRS (Bone 1996).

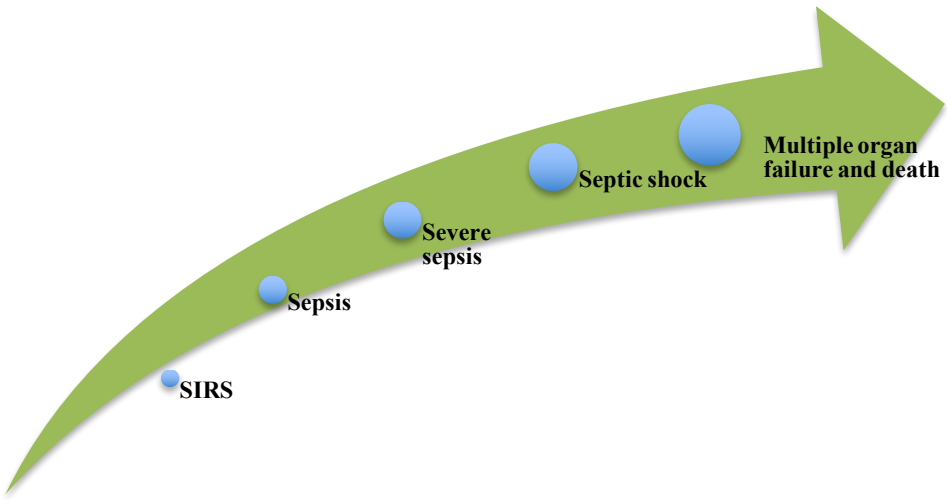

Figure 20:Progression of SIRS. sepsis (SIRS + infection), severe sepsis (organ dysfunction, hypotension and hypoperfusion), septic shock(severe sepsis+ hypotension) and multiple organ failure (2 or more organ failing).

The intensity and time course of SIRS is influenced by a balance situation between pro-inflammatory and anti-inflammatory cytokines at the local site of the inflammation (figure 21). The body reacts to this phenomena by the activation of reaction process called counter inflammatory response syndrome(CARS)which limits the duration of SIRS to avoid any further complications (Jaffer 2010).

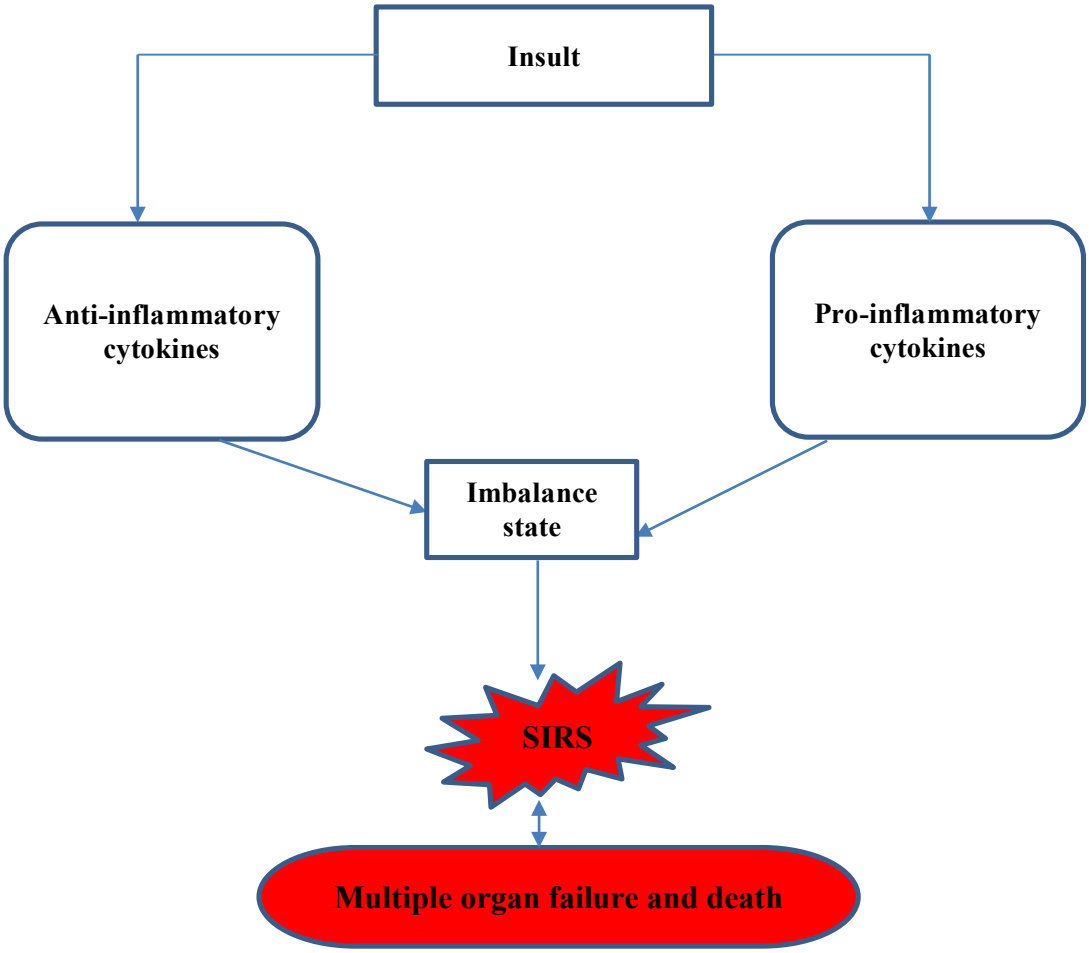

Figure 21:Balance between pro-inflammatory and anti-inflammatory cytokines. Adopted from (Jaffer 2010).

2.12 Summary

1. CPB deployment is associated with the development of SIRS as a response to the early contact between the blood and non-endothelial cell surface of CPB equipment. Also, ischemia resulting from CPB deployment, post-CPB reperfusion injury, the release of endotoxins from the gut and surgical trauma are key contributors to the onset of SIRS.
2. These factors initiate different cellular and humoral inflammatory cascades which activate the innate immune system to release pro-inflammatory and anti-inflammatory cytokines.

3. Downstream upregulation of these pro-inflammatory and anti-inflammatory cytokines triggers SIRS and results in severe deleterious post-surgical outcomes.
4. The current approaches to attenuate SIRS are classified into three main groups: surgery without CPB, technical modifications to the CPB and the administration of pharmacological agents such as aprotinin and steroids.
5. The literature demonstrated that these strategies are not patient-specific. We suggest that diagnostic modalities may be implemented prior to the surgery that can predict a subset of at-risk patients.

.

Chapter 3: Hypothesis and objectives of the work

3 : Hypothesis and objectives of the work

3.1 Introduction

CPB is the technique employed during open heart surgery as a temporary substitute for the patient's heart and lungs, diverting blood from the systemic circulation through an extracorporeal system, to allow the blood to be oxygenated and returned to the patient (figure 22and figure 23).

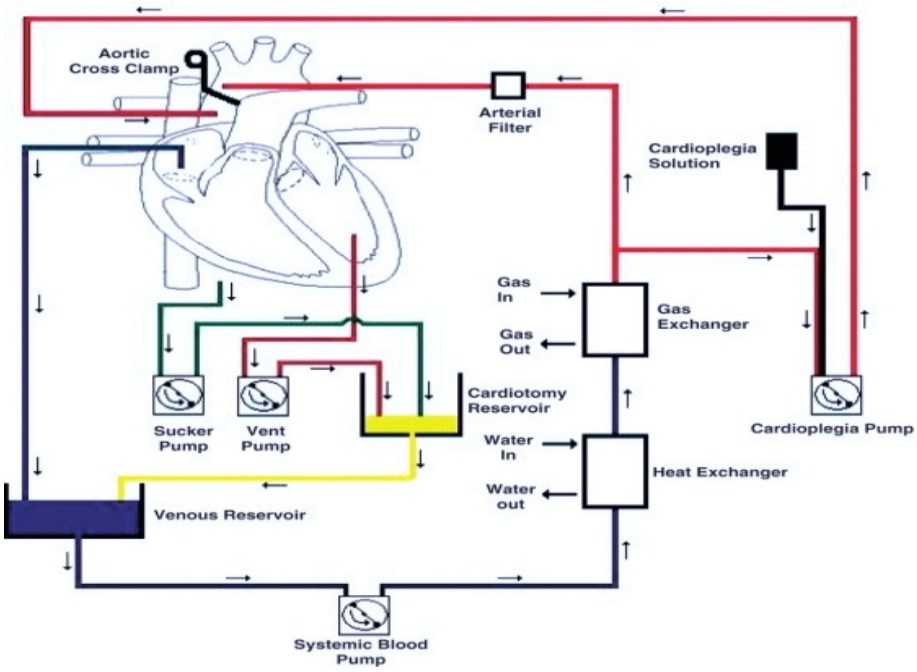

Figure 22:Diagram of a typical CPB system in use in operating. Showing the complexity of the apparatus(Bennett et al. 2015).

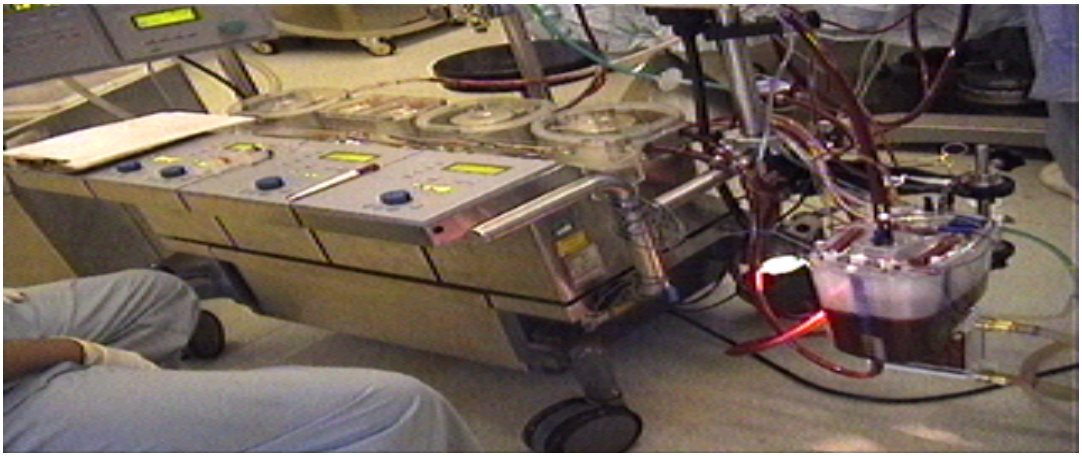

Figure 23:CPB in the theatre.

CPB is a complex system that can comprises very large surface areas of foreign materials such as PVC, polyamide, polyurethane, stainless steel, and aluminum (Asimakopoulos 2003) with which the patient's blood continually contacts. The extracorporeal surface area varies, but generally blood will come into contact with up to 12 m^2 of these foreign materials. CPB has been the underpinning technology for open heart surgery for over half of a century and its associated pathophysiology has been intensively studied throughout that time. However, the relationship between the blood- foreign materials contact and the triggering of a deleterious immune response was not identified until the mid 1970's (John Bulter 1993). In the ensuing years a number of strategies, were attempted to moderate the immune response to CPB. These largely fall into two categories, advancement of medical technologies and the administration of drugs, aimed at either suppressing or minimizing the impact of the immune response. These approaches include; the application of surface treatments to the surface of the blood contacting materials, typically using materials that are either inhibitory or biomimetic (Gunaydin et al. 2010) to moderate its contact mediated initiation; filtration technologies, particularly leukocyte filters which remove activated neutrophils in an effort to prevent their interaction with the endothelium, a key step in the immune response; non-specific kallikrein inhibitory drugs which inhibit neutrophil transmigration; mini-CPB systems which reduce the CPB system contact surface area and extent of haemodilution. These approaches to moderating and preventing the impact of the immune response to CPB during open heart surgery are based on sound laboratory evidence (Gourlay et al. 2001; Sun et al. 2013; Yii et al. 1996), and have been associated with some degree of improvement in recovery in the wider patient population as measured by established outcome measures

(Gunaydin et al. 2009).However, despite some fairly clear clinical evidence of a general clinical advantage associated with technologies, there remain a number of challenges associated with their deployment. In particular, these are expensive technologies, certainly too expensive to be generally deployed in all open heart surgery patients, particularly as most patients, with or without these devices tend to fare well in modern clinical practice. The current trend with these new techniques is to deploy them in "high-risk" patients, generally older, female, and re-do patient cohorts. However, it is unclear whether there is a true relationship between risk scoring in the conventional sense and the occurrence of heightened immune complications. Rather, the challenge of controlling the heightened immune reaction to CPB is currently unpredictable and does not correlate with current scoring or patient stratification techniques. Bearing this in mind, there is a dilemma in reducing the impact of the heightened immune response, and that is, in the absence of any accurate scoring or screening technique, the only approach to mitigating its impact given current inability to stratify patients for this specific risk, is to apply all of the moderating techniques and technologies to all patients. This is economically challenging for a national healthcare economy, and would impact considerably on the cost of open heart surgery globally. In recognition of the potential benefit of these technologies, a more appropriate approach to their deployment would be to adopt a more bespoke strategy, targeted at those patients who are predisposed to the inflammatory responses. Presently, we are not able to predict which of the general patient population fall into this heightened inflammatory responses category. However, there is evidence that as the patient population presenting for open heart surgery is increasing, particularly at the extremes of age, and the risk of

inflammatory mediated complications is also increasing (Davis et al .2004). It is clear that some form of screening technology would be of great benefit to the open heart surgery community, reducing the risk to patients with heightened propensity for immune response and reducing the cost to the healthcare providers by enabling the targeting of anti-immune strategies rather than encouraging ethical general deployment of these. In addition, considerable savings can be made by reducing the need for extended intensive tension unit length of stay for patients recovering from heightened immune response. This can be a considerable cost, with patients languishing in ITU facilities and costing healthcare providers upwards of 2000 euro per day(Tan et al. 2012).

3.2 Hypothesis of the project

Biomaterial activated cytokines can be employed in a screening test for the propensity of patients undergoing open-heart surgery to develop a heightened response to the intervention.

3.3 Aims and objectives of the project

The project aims to develop a screening technology which will enable the identification of patients with a heightened immune response before they undergo the open heart surgery procedure. The overwhelming problem with currently available anti-inflammatory strategies as we have discussed is our current inability to carefully measure and account for how an individual patient will respond to CPB from the perspective of the immune response. There is an enormous variability in this response. Whenever a study demonstrating lack of clinical effect of a theoretically promising strategy or significant contribution to the clinical outcome is discussed, we should wonder whether the patient population is of high or low enough risk and if the

individual biological variability is fully or equally accounted in the design. We need to focus our research efforts to better understand patients' biologic profiles before choosing a specific treatment strategy, in full knowledge of the fact that contact with the CPB system will elicit an immune response. This may avoid the current relatively crude, blind and potentially expensive, broad and unfocused application of mechanical, technical and pharmacological approaches to a biologically diverse patient population. Key to the successful deployment of expensive technological or pharmaceutical anti-inflammatory strategies is the identification of the patients for whom this will be of benefit, or indeed life sparing. Currently there are no procedures which enable the identification of these patients prior to surgery, rather the approach currently taken in normal clinical practice which is to treat the patients after surgery, but in the cohort of patients with a greatly heightened inflammatory response to CPB, this approach is both expensive in terms of intensive care unit time and is often unsuccessful. This project suggests a new approach to identifying these patients, through the development of a novel technology which will measure the propensity for inflammatory response to blood contact with extracorporeal systems. The overall focus of this work is in the cardiopulmonary bypass domain, but other treatments and interventional modalities in which tissues, in particular blood, comes into contact with foreign surfaces may also benefit. These might include renal dialysis, haemofiltration and possibly implantation of orthopaedic prosthesis where heightened immune processes are a known failure mode.

3.4 Objectives

1. To study the effect of DEHP Plasticised PVC and liquid DEHP in the initiation of inflammatory response on bovine blood and measure the response in terms of IL-6 and TNF-α.
2. To determine the effect of different agitation times in the upregulation of pro-inflammatory cytokines.
3. To conduct a clinical study to investigate the clinical impact of DEHP plasticised PVC and liquid DEHP initiators on the patients' blood samples prior to the surgery. The results were expressed in terms of the rapid pro-inflammatory cytokines (IL-6,TNF-α and C-reactive protein).
4. To determine the most appropriate and sensitive pro-inflammatory marker from the three rapid cytokines by using the suitable statistical methodologies.
5. To specify the most appropriate initiator (DEHP plasticised PVC/liquid DEHP) based on the laboratory and clinical studies.
6. To specify the most suitable approach to measure the heightened cytokine marker based on using two measurements methods (ELISA and FTIR).
7. To develop the screening test technology for measuring the heightened inflammatory marker.

Chapter 4: In-vitro laboratory methodology

4 : In-vitro laboratory studies methodology

4.1 Background

Cardiac surgery with a supportive heart lung machine promotes the initiation of cellular and humoral interactions that lead to produce unwanted complications after the operation. Cytokines are considered as the essential humoral components that initiate the immune system to achieve a systemic balance through the secretion of pro-inflammatory and anti-inflammatory cytokines. However, overexpression of cytokine species leads to a systemic imbalance leading to the development of a systemic inflammatory response syndrome (SIRS). When this amplified response is uncontrolled, it can progress to multiple organ failure and death. The initiator of this syndrome can be multi-factorial and it is unpredictable in the clinical setting.

The aim of this work is therefore to develop a predictive diagnostic device that can enable the clinicians to identify high risk patients prior to the surgery. Such a device may reduce the number of patients who go on to have SIRS as a response to the procedure by directing them to alternative strategies. To achieve this aim, it is essential to identify the best indicator of the syndrome in the blood. Based on the literature review (Giannoudis et al. 2008) stated that IL-6 is a good indicator of inflammation and is overexpressed in patients who may develop SIRS. However, there are a number of cytokines that may also present prognostic targets and these also need investigation.

The present work will study the response of these cytokines to inflammation stimuli (IL-6 and TNF-α). Several studies supported the importance of these pro-inflammatory cytokines and their major role in the mediation of the inflammatory responses due to their rapid appearance in the blood during the inflammation cycle.

For example, Meng and his research group performed a clinical study on fourty patients and stated that IL-6 with TNF-α levels were increased significantly one hour after the cessation of CPB and reached peak within 6 hours (Meng et al. 2008). The below table summarizes these cytokines and their functions.

Cytokines	Peak time	Function
TNF-α	Peak about 1 hours after cessation of cardiopulmonary bypass	• Initiating the production of other pro-inflammatory cytokines such as IL-1 and IL-6 • Induction of hepatic acute phase • Endothelial dysfunctions • Stimulation f adhesion molecules phases
IL-6	Increase levels after 1 hours of the CPB and peak after 4 hours	• Induction of acute phase of inflammation • Strong correlation between the peak level and post-operative outcomes (ischemic)

Table 3:The common pro-inflammatory cytokines and their functions(Meng et al. 2008).

Materials and Methods

The basis of this diagnostic device is to measure the upregulation of cytokines (IL-6, TNF-α and C-reactive protein) in response to an inflammatory stimulus to a sample of blood. The device should be capable of indicating overexpression of the cytokines in response to the stimulus, thus indicating the at-risk patients (see schematic below).

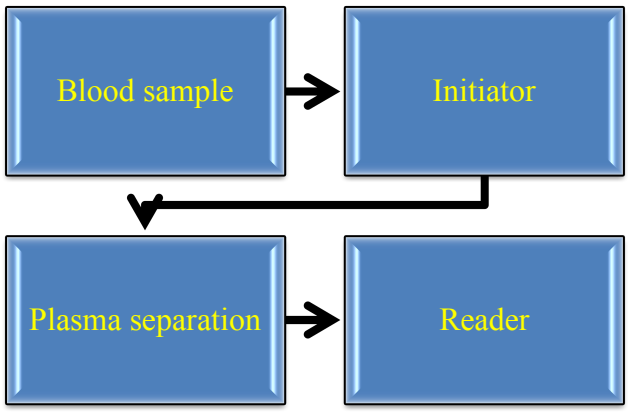

Figure 24:Schematic diagram of the laboratory work process.

The combination of initiator and selected cytokine should ideally produce an early rapid and measurable response. It is desirable that the instrument should be capable of delivering a near real time measure of this response. However, before developing the device itself the current work focused on ascertaining the best combination of the initiator and the cytokine. For this purpose, as previously discussed, we selected IL-6 ,TNF-α as the targeted markers of inflammation and DEHP plasticised PVC and DEHP itself as the initiators.

4.1.1 Initiators

The medical literature has shown that there are a number of materials, both synthetic and biological, that can trigger the inflammatory response in the blood (Lappegård et al. 2008). However, in the context of cardiac surgery we consider it important that the initiator should be one that the blood will commonly come into contact with during the surgical procedure to eliminate any false positive results. Recent studies have shown that PVC, more specifically DEHP has significant pro-inflammatory properties and is a major element of the cardiopulmonary bypass circuitry (Gourlay et al. 2001; Gourlay et al. 2010; Gourlay et al. 2003). It is for this reason PVC and DEHP were selected as the initiators in the study. Both DEHP plasticiser PVC and DEHP itself were selected for a number of purposes, but primarily to ascertain whether there is any added value using the solid PVC material as it may be safer to use in the final device configuration. In addition, as the previous studies did not investigate the effect of employing different amount of PVC and liquid DEHP to the blood in terms of the upregulation levels of the targeted molecules (IL-6 and TNF-α), the present study covers different PVC weights and different liquid DEHP volumes as see in section 4.4.

Polyvinyl chloride (PVC)

The concept plasticiser means a substance that is added to materials such as plastic to make it felxible resilient and easy to use in many applications. There are more than 300 types of plasticisers but the common types are phthalates and adipates.

PVC is a rigid material in its nature due to a short distance between molecules.However, when adding plasticiser to the PVC,the distance between molecules becomes wider and the material becomes softer .

PVC is the third most produced synthetic plastic polymer, after polyethelene and polypropylene and it has been shown to be associated with the initiation of inflammatory responses(Gourlay et al. 2003).

For the purpose of this work, ground DEHP plasticised PVC will be used, derived from medical grade PVC tubing. This configuration was selected due to the fact that in this state, it presents a high surface area for interaction with the blood, to take place and thus may result in a relatively low volume of final activator product for using the diagnostic device.

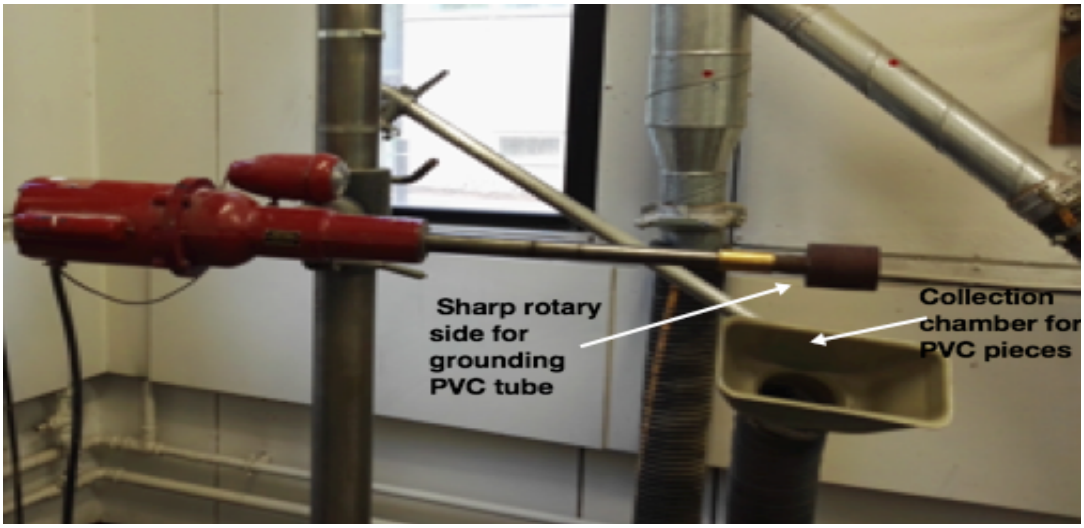

Figure 25:Image of the ground machine that used to ground DEHP plasticised PVC tube (source: biomedical engineering department workshop, University of Strathclyde).The tube is placed on the sharp edge of the machine and it is rotated a clockwise direction to produce a small grounded pieces of DEHP plasticised PVC.

DEHP

DEHP is the most common plasticiser used in medical applications. Di-(2-ethylhexyl) phthalate is an endocrine disruption chemical used worldwide as a plasticiser for medical and non-medical applications. It is known as phathlates and is used to make the tube softer and more flexible (Sampson and De Korte 2011).This chemical can produce several toxic effects to the blood and is considered as an initiator of the inflammatory responses (Chang, Lin, and Chang 2013). However, its toxic effects continues to be investigated. A study suggested that its effect are of little importance in short term adult CPB but they are more significant where the body mass ratio is much higher (Gourlay 2001). On the other hand, DEHP does produce an innate inflammatory response during CPB surgery.A study conducted by Zhao demonstrated the effect of the presence of DEHP in the initiation of the inflammatory response.Interestingly, the reduction of the DEHP resulted in the reduction of the fibrinogen adsorption on the material surface which reduced the impact of inflammatory mediators in terms of the SIRS development (Zhao and Courtney 1999).

As outlined above, both DEHP plasticised PVC and DEHP itself may represent controllable and relevant initiators for a diagnostic/prognostic tool. A series of experiments was therefore designed to test this hypothesis and determine the best initiator.

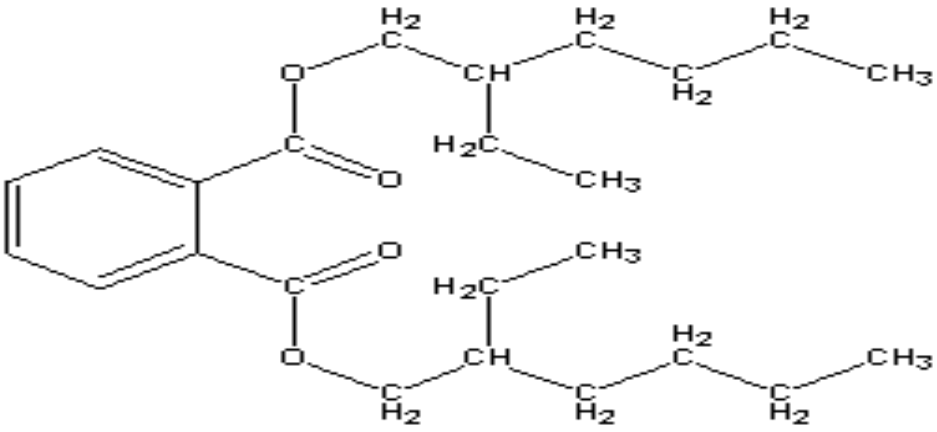

Figure 26:DEHP molecule structure **(Taken from: http://wwwcourses.sens.buffalo.edu/)**

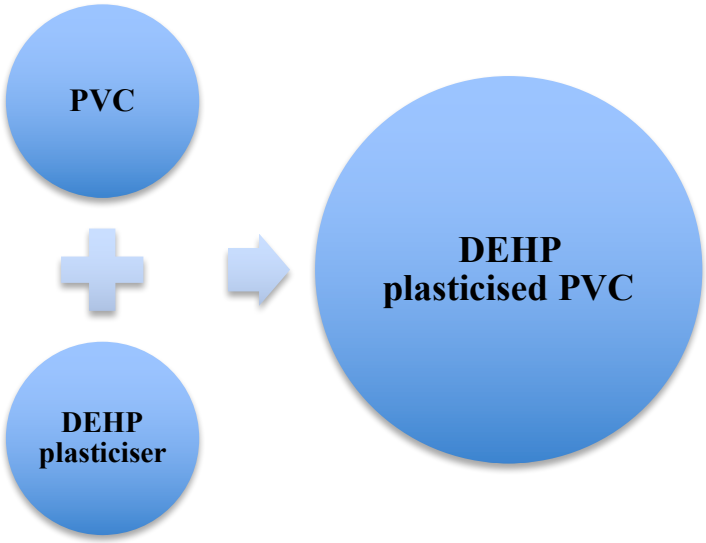

Figure 27:The formation of DEHP plasticised PVC .

4.2 Determination of the initiators

A series of experiments were carried out in the laboratory to determine whether liquid DEHP itself or DEHP plasticiser represent the most predictable and sensitive initiator of the upregulation of pro-inflammatory cytokines in the blood. Different quantities of both DEHP itself and DEHP plasticiser were employed in these experiments with the objective of determining the effect of quantity and response in order that the smallest quantity of material can be employed in the final device configuration. In addition, the optimal exposure time was investigated at all levels of

material exposure to determine the best agitation time for the final device configuration.

4.3 Blood samples

Bovine blood was obtained according to established procedure in our lab. It was brought to the lab on the same day of the experiment from the local abattoir using the following protocol table (table 4).

Steps	Description
1	Collect a bovine blood from the local abattoir (Sandyford farm,Paisley,UK) in a sealed 5L container immediately after animal was sacrificed.
2	In order to prevent clotting, the blood must be treated with 10,000IUs of heparin sodium from porcine mucosa (*Sigma Aldrich*)
3	This heparinisation is achieved by mixing heparin sodium with 50ml of 0.9% NaCl saline and placing this solution in the 5L container before the blood is collected.

Table 4:Bovine blood samples protocol.

4.4 Activation of blood samples

Blood samples (5 ml heparinized bovine blood) were placed in 6 well plate. The activating agent was introduced into the blood containing wells in accordance to the following exposure protocol (table 5). As shown in table 5, bovine blood was contacted with different weights of DEHP plasticised PVC and different volumes of liquid DEHP. They were agitated for different times (0 min, 10 min, 30 min, 60 min and 90 min) and samples were taken from each well in addition to the static and dynamic control samples.

Time (min)	DEHP Plasticised PVC (gram)						Liquid DEHP (ml)					
	0.5	0.4	0.3	0.2	0.1	0.05	0.5	0.4	0.3	0.2	0.1	0.05
0	✔	✔	✔	✔	✔	✔	✔	✔	✔	✔	✔	✔
10	✔	✔	✔	✔	✔	✔	✔	✔	✔	✔	✔	✔

90	✔	✔	✔	✔	✔	✔	✔	✔	✔	✔	✔	✔

Table 5:Exposure protocol of the bovine blood with DEHP plasticised PVC and liquid DEHP.

Static and dynamic control samples were introduced into the experiment but with no material exposure. Static control samples were placed in a 5 ml container with no agitation while dynamic control samples were placed in 6 well plate and agitated with an orbital shaker. This experiment was carried out at room temperature and blood samples were taken in accordance to the following sample protocol table 6.

Time(min)	Description of the blood collection
0	1 ml blood is taken from each well by using 2 ml polycarbonate syringe and put in 1.5 ml eppendorf tube.
10	
30	
60	
90	

Table 6:Sampling time description.

The blood samples harvested from the process were centrifuged (using a servall pico centrifuge) immediately (13000 rpm for 10 min), the plasma was removed and snap-frozen, and then stored at -80°C for future analysis.

Figure 28:Bovine blood experiment set up from left to right (Centrifuge, orbital shaker, weight balance, liquid DEHP, ground DEHP plasticised PVC and blood samples).

4.5 Enzyme Linked Immunoassay Sorbent Assay (ELISA)

The plasma samples were defrosted and the concentration of the molecules of interest were measured using the ELISA technique.

The enzyme-linked immunosorbent assay (ELISA) is an immunological assay commonly used to measure antibodies, antigens, proteins and glycoproteins in biological samples. The technique since its first introduction to the medical field 40 years ago, has become a gold standard for the diagnosis of many diseases(Lequin 2005). Some examples include: diagnosis of HIV infection, pregnancy tests, and measurement of cytokine concentration in plasma and serum.

In an ELISA, an antigen must be immobilized to the micro plate wells and then attached with an antibody that is linked to an enzyme. For example, if we are looking for IL-6 cytokine in the plasma, the 96 wells of the microplate should be coated with IL-6 antibodies and then the assay process performed in order to capture only IL-6 while other cytokines will be removed by washing steps. Detection is accomplished by assessing the conjugated enzyme activity via incubation with a substrate to produce a measureable product in a color form (yellow). Subsequently, the optical density of this color is measured by using an appropriate spectrophotometer technique.

4.5.1 ELISA steps

The sandwich ELISA technique is accomplished via four essential steps: Coating, capturing, detection and measuring the absorbance as seen in figure 29. These steps are explained in details in table 7.

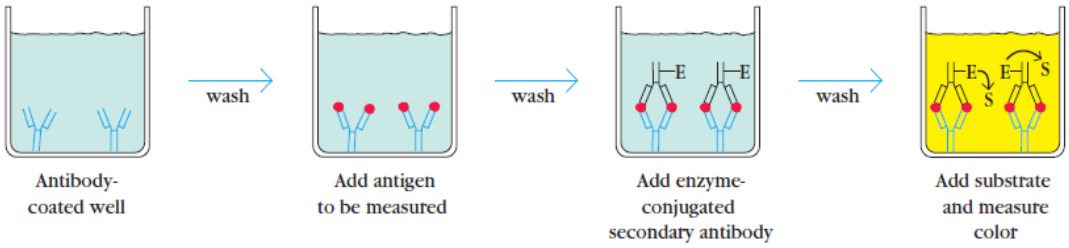

Figure 29:Sandwich ELISA general principle. **(Taken from http://laboratoryinfo.com/elisa/).**

Steps	Description
1	Coat the plate with the capture antibodies to allow capturing the targeted antibodies only and other antibodies are removed by washing.
2	Add all samples to the plate according to the planned experiment sheet.
3	Add detection antibodies to bind with the targeted antigen that already bound to the plate
4	Add substrate solution to stop the reactions and develop the color in the samples.
5	Place the plate into the plate reader to measure the samples absorbances.
6	Generate the standard curve based on the absorbance of the standard samples from the plate and known concentrations. then ,the concentration of each absorbance antigen can be calculated from the standard curve equation.

Table 7:Sandwich ELISA steps.

In this work, for both IL-6 and TNF-α , the bovine plasma samples were arranged in the ELISA microplate according to table 8. The adopted ELISA protocols for both IL-6 and TNF-α were bought from RD systems a biotechne brand, Abingdon Science Park UK. Details of the procedures are contained in the supplier data sheets, Appendix A.

			DEHP plasticized PVC					Liquid DEHP

Table 8: Bovine blood samples' distribution in the ELISA plate. From the table SC is the static control and DC is dynamic control.

All measurements were carried using three separate sources of blood, providing n=3. A spectrophotometric assay was used to determine the protein's concentration of

each sample using the reference calibration curves derived from the standard solutions.

4.5.2 Plate reader (spectrophotometer)

A multiscan spectrophotometer reader is an instrument used widely for many clinical and research purposes to measure the optical density of the yellow color of each well. Basically, a light source illuminates the sample at a specific wavelength and the light detector is located at the other side of the well to measure the actual transmitted light via the sample (Figure 30). The specific wavelength is adjusted from a computer control interface system via a specific software of the technique. For example, in ELISA, the most recommended wavelength for cytokines IL-6,TNF-α is 450nm.

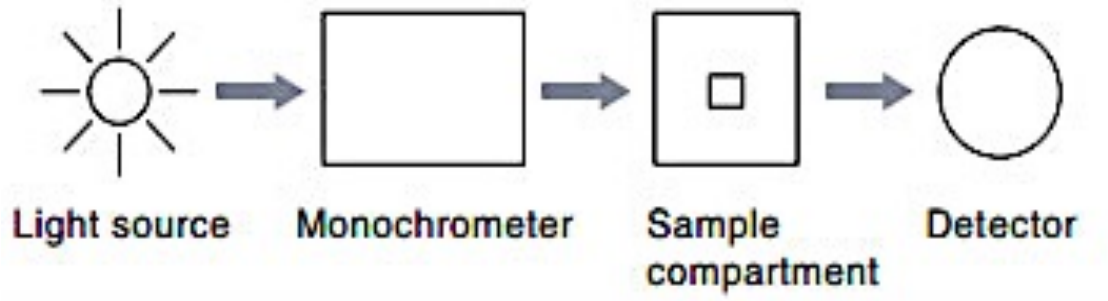

Figure 30:Spectrophotometer principle of operation. **(Taken from http://www.shimadzu.com)**

Spectrophotometer components:

Light source

It is required to be stable over the time and should be bright across the wide range of wavelengths. The commonly used light source in spectrophotometers are halogen and deuterium lamps due to their visibility and long service life.

Monochrometer

Unlike spectrometer technique which allows the process of capturing the whole light spectrum at different wavelengths across the sample, monochrometer narrows the capturing area. It is used to measure the intensity of light via capturing a specific spectrum at particular wavelengths.

Sample compartment

Fundamentally, the spectrophotometer technique is based on the theory of splitting the emitting light into different components at different wavelengths that can pass over the sample, and detecting it by a specific silicon or photomultiplier detector at the end of the process.

Detector

Simple silicon or photomultiplier detectors can be used for ultraviolet and visible light range. It is the last element of the spectrophotometer and it can measure the intensity of the absorbed light via the samples.

Description of the plate reader software and how it measures absorbance

Spectrophotometer is connected to a computer interface system in order to control all functions and adjustments by a powered software for this purpose (figure 31). Ascent multiscan software provides a wide range of measuring different spectral wavelengths from 340-850 nm. The system is also designed to measure the absorbances of either 96 wells or 384 wells. It is possible to generate results within 9 seconds for 96 wells and 20 seconds for 348 well plate.

In this work, the measurements were done according to the following steps (table 9).

Steps	Description
1	Set the specific wavelengths for the measurement (450 nm and 540 nm). The recommended wavelengths for IL-6 and TNF-α is 450 nm. According to the provided protocol , the obtained optical density at 450 nm will be corrected to be more accurate by substrate the optical density at 540 nm from the 450 nm (see appendix A for RD bioscience ELISA protocol).
2	Insert the 96 wells plate into the reader.
3	Run the analysis and wait for 9 seconds to get the results.
4	Copy the results into spreadsheet file and save it for future analysis.

Table 9:Multiscan plate reader steps

Figure 31:Multiscan plate reader and the computer interface system.

Standard curve

The ELISA standard curve is prepared by making serial dilutions of standard samples with known concentrations from the stock solution according to the provided protocol from the supplier (RD systems a biotechne brand, Abingdon Science Park, UK).The standard solution should covers the full standard range. Practically, the standard samples should be prepared prior to the experiment and used immediately.

After getting the absorbances from the plate reader, the standard curve is constructed by plotting the mean absorbance of each standard against the known concentration.

Then, we can add trendline and display R^2 with the curve equation. Higher R^2 indicates the best fit of the curve and the mathematical equation of the curve was used to calculate the concentration for each sample.

4.6 Statistical analysis

The samples' absorbances were measured three times by ELISA to ensure precision and accuracy of the measurments. Hence, the results are presented as mean± SEM. Statistical significance is specified by paired t-test ($p<0.05$).

4.7 Summary

1. A series of in-vitro laboratory studies will investigate the effect of employing two initiators (DEHP plasticised PVC and liquid DEHP) with bovine blood samples.
2. The response was measured in terms of IL-6 and TNF-α levels by using the ELISA technique.

Chapter 5: In-vitro laboratory results

5 : In-vitro laboratory studies results

5.1 Introduction

The objective of this aspect of the work was to determine the impact of two potential initiators of the inflammatory response (ground DEHP plasticised PVC and liquid DEHP) in constrained blood samples, to determine whether there is a dose response to the exposure and to investigate the impact of the activation process on two cytokines, IL-6 and TNF-α. This work was carried out in a series of in-vitro experiments using fresh heparinized bovine blood. The primary objective of this aspect of the thesis was to determine the most appropriate initiator and marker for the intended screening technology.

5.2 IL-6 measurments

Standard curves were generated based on the standards provided in the commercial assay kits. This standard curve and the associated trendline equation were used to calculate IL-6 concentration in each sample (figure 32).

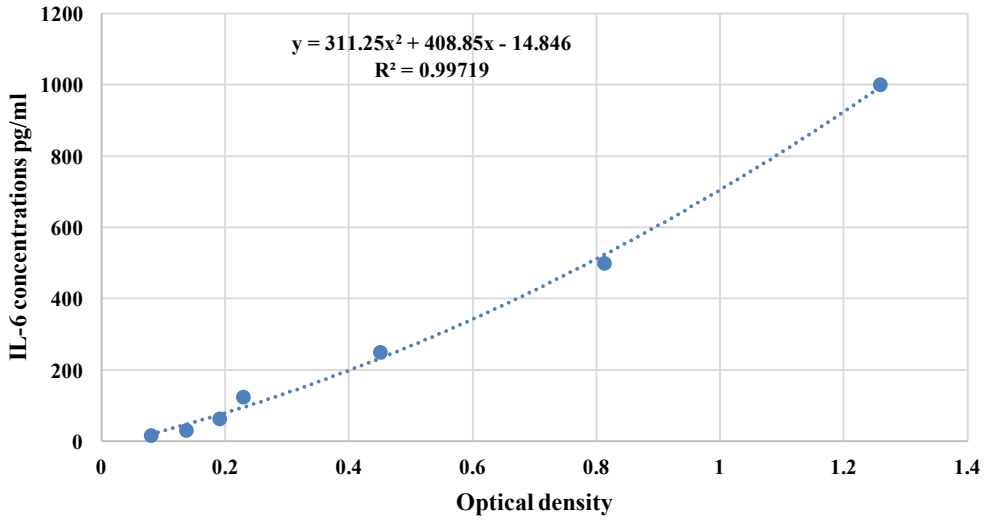

Figure 32:Representative IL-6 standard curve. All IL-6 standard curves can be seen in appendix B.

The activation process was carried out on all samples with parallel with static and dynamic control samples as described in the study protocol earlier in chapter 4. Control samples were used to determine the significant effect of different agitation times and the results of these processes are expressed in figure 33, 34 and 35 and 36,37 and 38.

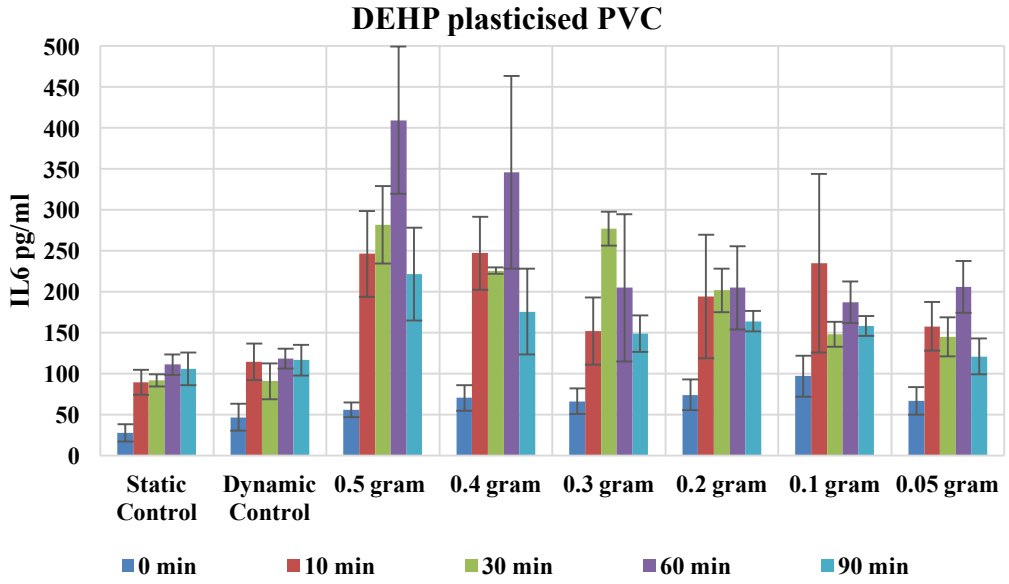

Figure 33:IL-6 levels pg/ml with grounded DEHP plasticised PVC at different agitation times (n=3).

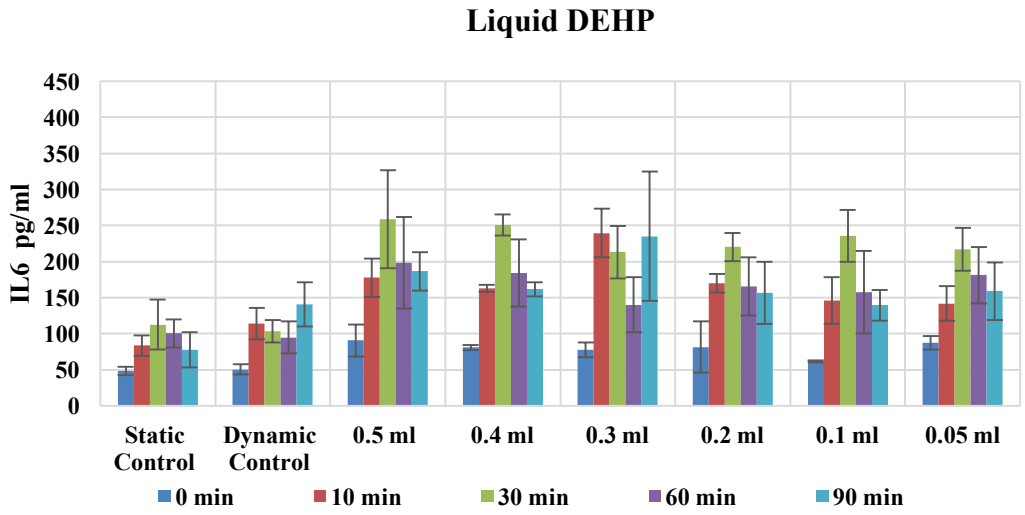

Figure 34:IL-6 concentrations pg/ml versus the mean of different loading liquid DEHP at different agitation times (n=3).

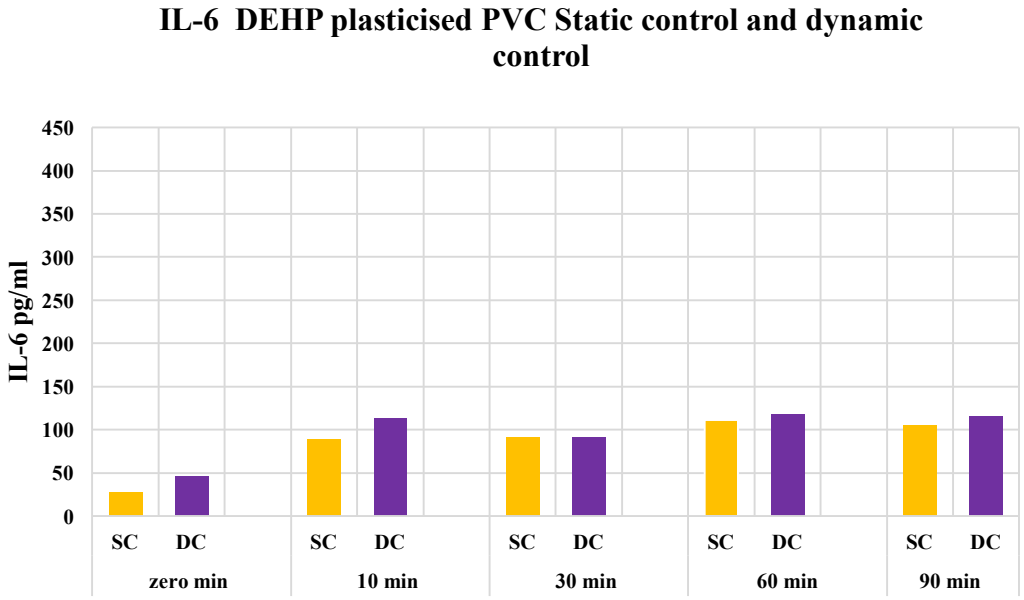

Figure 35:Static control(SC) and dynamic control (DC) IL-6 levels (DEHP plasticised PVC samples

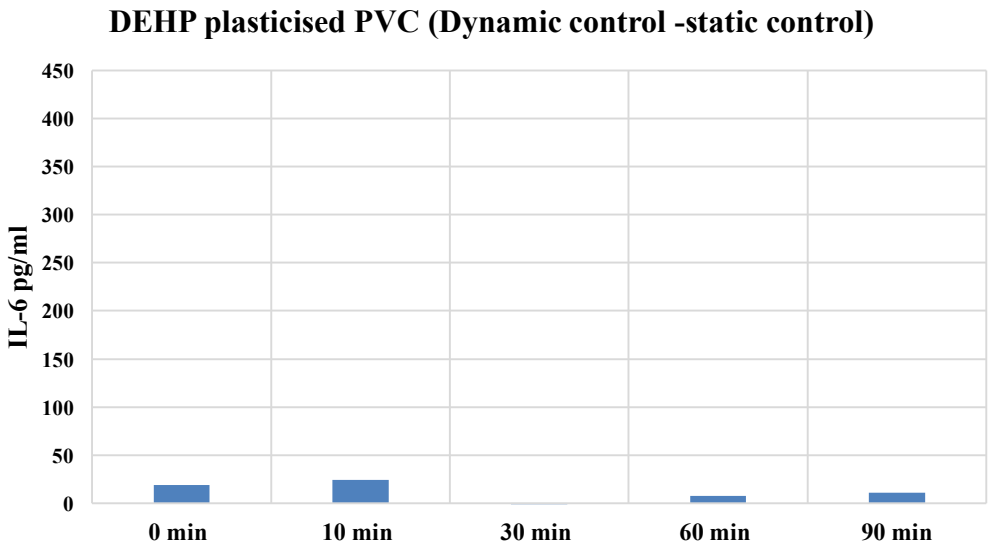

Figure 36:Dynamic controls minus static controls (IL-6 DEHP plasticised PVC).

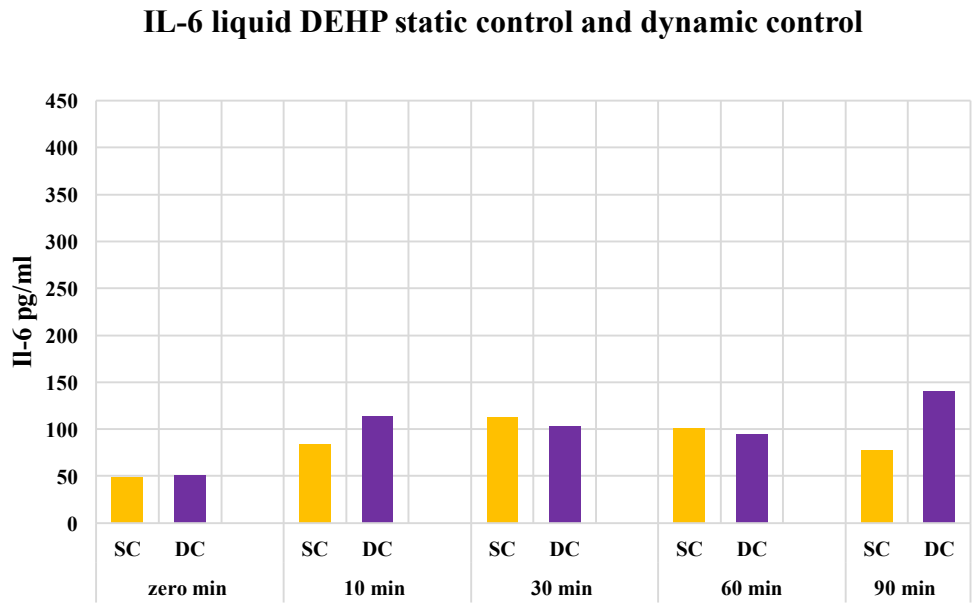

Figure 37:Static control(SC) and dynamic control (DC) IL-6 levels (liquid DEHP samples).

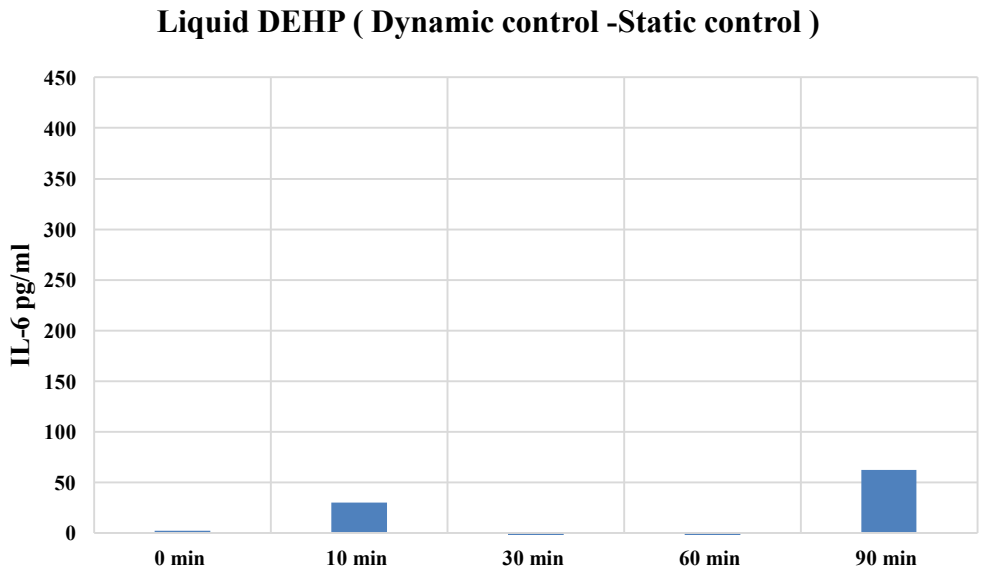

Figure 38:Dynamic controls and static controls (IL-6 liquid DEHP).

It can be seen from the above figures that there is a variation in response to different agitation times and weights and volumes of initiators. These outcomes suggested that both initiators are associated with the upregulation of IL-6 levels across the agitation times. Interstingly, statistical analysis of these data t-test showed statistical

significance with increasing weights and volumes of initiators, with the most significnt differences associated with the highest weight and volume levels (0.4 gram DEHP plasticised PVC (p=0.0005)and 0.4 ml liquid DEHP (p=0.0004) after 30 min agitation time. Control samples confirmed lower IL-6 levels which suggest a strong effect of the initiators in the upregulation of IL-6 concentrations.

5.3 TNF-α measurements

Similar to the IL-6 measurements in this study, TNF-α standard curves were generated according to the ELISA protocol in order to calculate the concentration levels of each sample, figure 39.

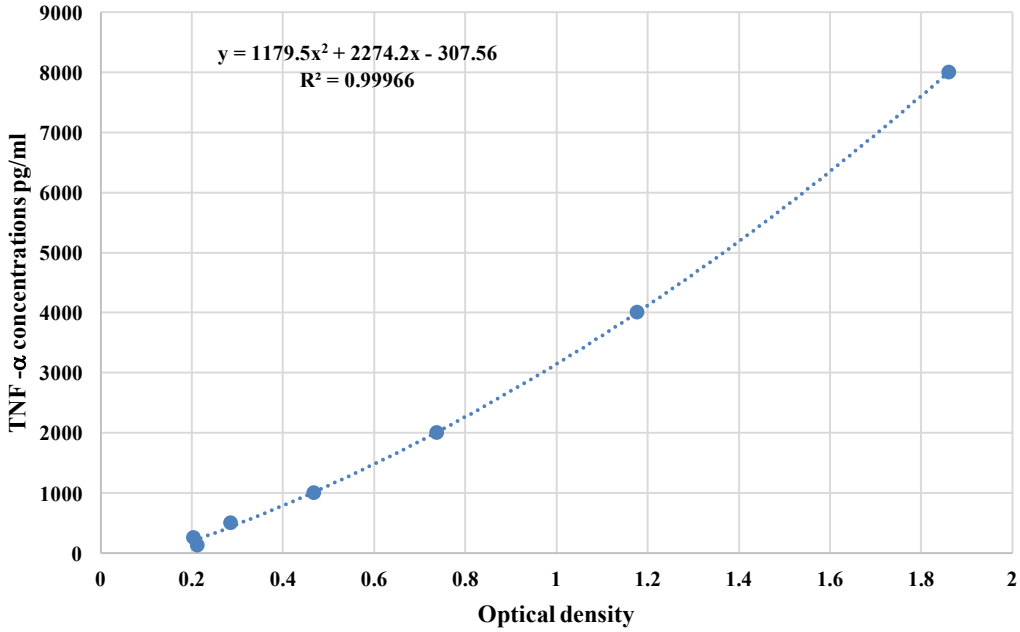

Figure 39: Representative TNF-α standard curve . All TNF-α standard curves can be seen in appendix C.

TNF-α results were expressed in the following figures (40,41,42,43,44 and 45). The activation process of all samples were performed as the outlined explained protocol in chapter 4.

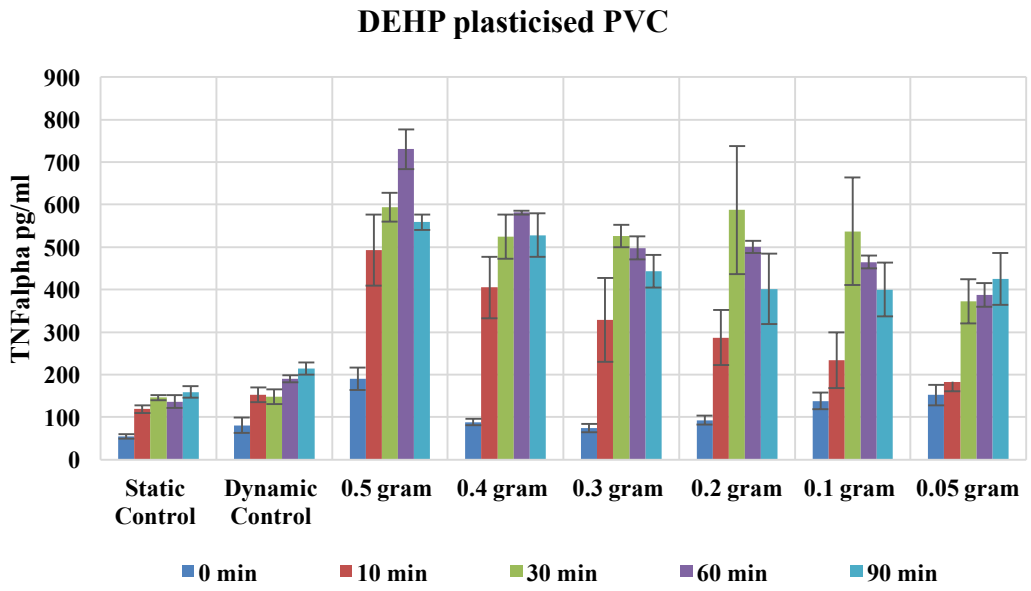

Figure 40:TNF-α concentrations pg/ml versus different weights of DEHP plasticised PVC at different agitation times (n=3).

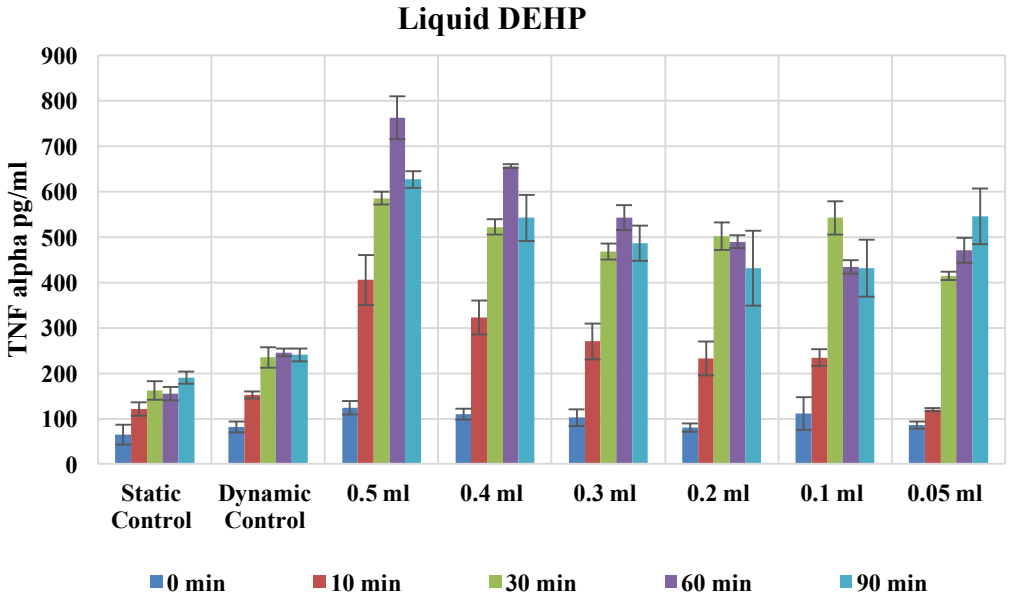

Figure 41:TNF-α concentrations versus different liquid DEHP volume at different agitation times (n=3).

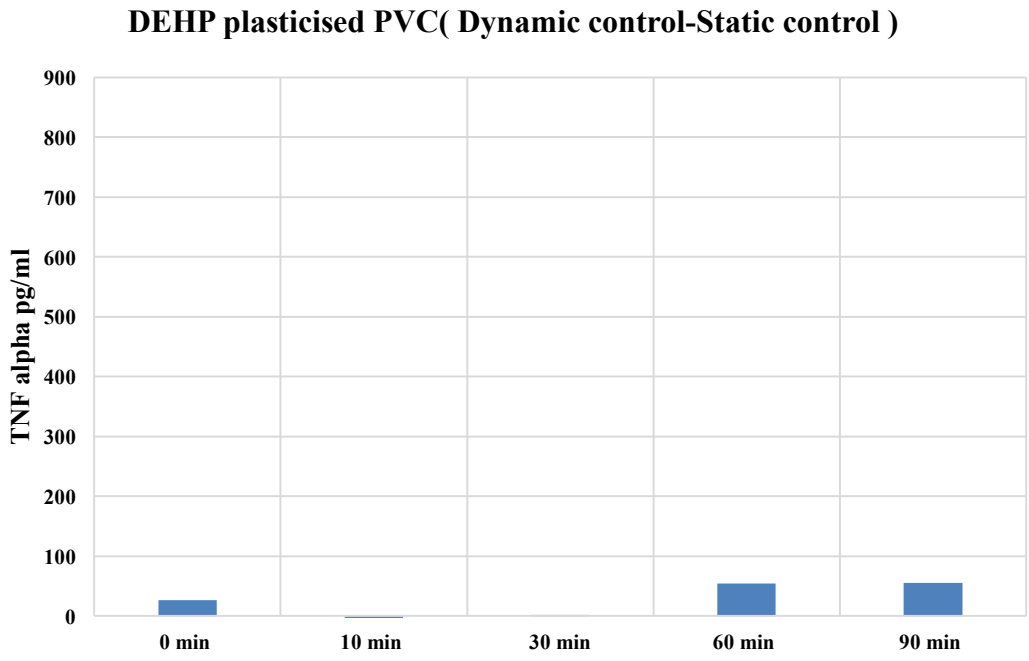

Figure 43:Dynamic control minus static control values (TNF-α DEHP plasticised PVC) .

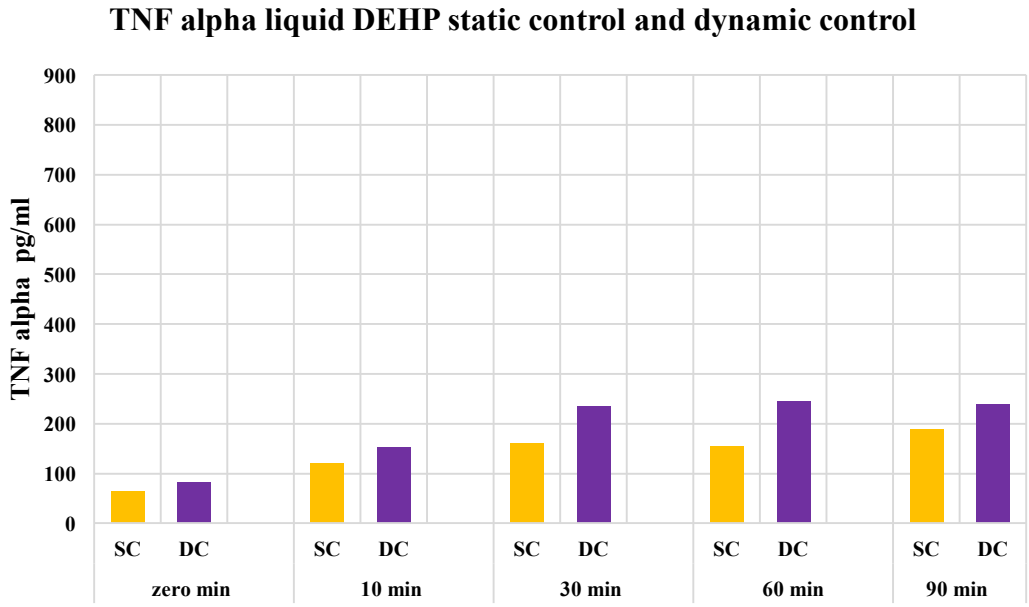

Figure 44:Static and dynamic control samples (TNF-α liquid DEHP).

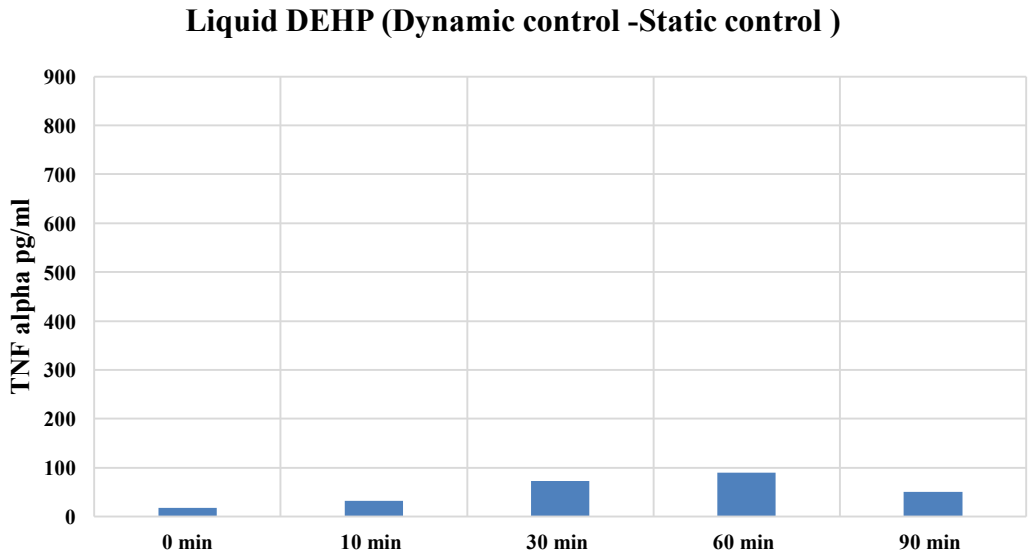

Figure 45:Dynamic controls minus static controls (TNF-α liquid DEHP).

From the above figures ,TNF-α with both initiators (DEHP plasticised PVC and liquid DEHP) confirmed a response which demonstrates an activation process for this cytokine with exposure to the initiator. T-test analysis was performed across the in different weights and volumes of initiators. In common with the study of IL-6,

TNF-α shows an upregulation associated with exposure and further suggests that higher weights and volumes of initiator are associated with a greater response, the most significant responses were observed with 0.5 gram, 0.4 gram and 0.3 gram DEHP plasticised PVC and 0.5 ml ,0.4 ml and 0.3 ml liquid DEHP $p<0.005$ in all cases when compared to baseline. These levels were correlated with agitation time starting from 30 min onwards.

Static and dynamic control samples as compare to the other samples with initiators showed lower levels and the difference between control samples as seen in figure 43 and figure 45 confirmed the effect of initiators in the expression of the cytokine of interest.

5.4 Summary

1. IL-6 and TNF-α results suggested that DEHP plasticised PVC and liquid DEHP itself are considered as pro-inflammatory initiators leading to the triggering of inflammatory cascades in the blood.
2. Exposing blood to different weights of DEHP plasticised PVC and liquid DEHP showed a significant increase in the cytokine levels. Higher weights and volumes are associated with higher overexpression peaks of IL-6 and TNF-α.
3. The optimal agitation time which is associated with the upregulation of both cytokines occurs starting from 30 min onwards.

Chapter 6: Clinical study methodology

6 : Clinical study methodology

6.1 Objectives

The objective of this section of the current project is to determine a number of factors relating to the suitability of our proposed approach to assessing the propensity for patients to exhibit a heightened inflammatory response to open-heart surgery, prior to the operative procedure. These factors include the following;

1. The most appropriate plasma marker.

2. The most appropriate initiator

3. The most appropriate detector approach

4. The correlation between measured cytokine species and adverse clinical outcomes of known inflammatory origin.

Although a similar, very small scale study, had been carried out in the past by this research group, highlighting some degree of correlation between measured IL-6 in contact activated blood samples and clinical outcome (Gourlay 2006), it was thought essential to repeat this procedure on a larger scale under similar clinical conditions and using additional potential markers and initiators to ensure that we see the same effect and to optimize the overall process. To this end, in the present study we investigated the upregulation of the following plasma markers of the inflammatory response and blood initiators:

Initiators

1. Ground DEHP plasticised PVC
2. Liquid DEHP

Markers

1. IL-6
2. TNF-α
3. CRP

Two methods of measuring the markers in the blood samples were utilized to identify the quickest and most suitable approach in terms of delivering a clinical device for patient screening. In addition to assessing the most appropriate technique in terms of processing time, the results of these studies will enable the assessment of the correlation between the two techniques in terms of measured values. The two techniques employed were, conventional enzyme linked immunosorbent assay ELISA measurement and Fourier Transform Infrared Spectroscopy (FTIR). Both of these techniques are widely available, used in the measurement of biological markers, but differ in terms of the complexity of the process and the time from sample collection to data output.

6.1.1 ELISA assay technique

The ELISA technique is now considered to be the industry standard for the measurement of biomolecules in blood, both under laboratory and clinical conditions. The technique has been described in detail in chapter 4, but is considered to be an accurate methodology in this field. The kits required to perform ELISA assays are commercially available and are relatively easy to perform. However, the technique is somewhat complex, requires multiple steps and is very time consuming. Most laboratory ELISA assays take in excess of 8 hours to complete and derive data. Despite the complexity of the ELISA approach, the reliability of this technique suggests that it may lend itself to the development of a handheld device for molecular measurement in the field.

6.1.2 Fourier Transform Infrared Spectroscopy (FTIR)

FTIR is a rapid, label free and non-destructive technique for the measurement of a broad range of molecules, both of biological and non-biological origin. Currently its

most important area of application is in measuring the fingerprint region (very small quantity)(Baker et al. 2014), but its use in biomarker detection is growing significantly, particularly in the detection of cancers (Diem, Griffiths, and Chalmers 2008; Bellisola and Sorio 2012; Farhane et al. 2015). The technique, carried out on plasma or serum samples generally, produces multiple spectrums with high sensitivity that identify various molecular markers in the sample.

Both techniques generate molecular measurement of various species and are dependent upon know concentrations of known molecules to create calibration curves for accurate measurement. In the context of the proposed POC assay device, both techniques offer some promise of success, but generally the FTIR technique is faster and requires fewer steps in the measurement process. However, ELISA is the laboratory standard against which any new technique must be measured and some high degree of correlation between a new technique such as FTIR and ELISA is essential if any degree of confidence in measurement can be obtained.

6.2 The clinical protocol

The clinical study was carried out at the University of Kirrikkale associated hospital in Ankara, Turkey under local ethics approval. The study was carried out on patients undergoing elective first time open heart surgery for a broad range of cardiovascular lesions, including coronary and valvular diseases. It is crucial to this project that we study sequential patients with no influence of procedure type or gender. The primary focus is to seen by assay the propensity of these patients to exhibit an inflammatory response prior to surgery and to assess those with an apparent heightened propensity in terms of the clinical signs of inflammatory impact in the post surgical period. As the focus of this work is to develop a screening assay technology, the peri-surgical

response was not considered and additional blood samples during the surgical procedure were not taken in an effort of mimic the actual intended clinical application of the device.

6.2.1 Patient Population

Patients undergoing first time elective open-heart surgery for the correction of coronary or valvular lesions were recruited to the study. These patients were sequential and all were recruited in accordance with the local ethics committee requirements. All patients provided written consent to the study. 52 patients were selected for the study, this number being determined by the available timeframe for the study.

6.2.2 Clinical Procedures

All patients underwent cardiopulmonary bypass supported open-heart surgey for the repair of either coronary or valvular lesions. The CPB system consisted of a roller pump with a membrane oxygenator (Dideco Compactflo Evo,Sorin Group.Miranfdola Modena ,Italy). A priming volume 1500 ml Isolyte-S (Ec-Baxter ,Istanbul,Turkey) was used to prime the system and a flow index of 2.4 was employed during the procedure. 5000 units of heparin was added. After anticoagulation with heparin (300U/kg), Activating clotting time (ACT) was kept over 400 seconds. Core temperature was reduced to 33°C during CPB and rewarmed at release of the aortic cross clamp. 1000 ml cardioplegia was employed with 500 ml given as an initial dose and further 500 ml doses given every 20 minutes. This is the standard CPB protocol at this clincal. During the procedures CPB time , aortic cross clamping time and other perfusion related metrics were recorded.

6.2.3 Patient Data Harvesting

The normal range of patient demographics were collected prior to surgery and broad surgical and perfusion parameters were recorded from the CPB record. Post-surgery the patients clinical course was recorded with an emphasis on markers of inflammatory response.

Patient Demographics

The following parameters were recorded;

Age (years)
Gender (Male/Female)
Height (cm)
Weight (kg)
BSA (m^2)
Operative Procedure
Euroscore (Low/Medium/High)

Table 10: Basic Patient Demographic Data collected.

Cardiopulmonary Bypass Parameters.

The following CPB parameters were recorded.

Blood Flow (L/min)
Cardiopulmonary Bypass Time (min)
Aortic Cross Clamp Time (min)
Patient Core Temperature (°C)
Volume of Fluid Transfused

Table 11:Basic CPB parameters recorded in all patients.

Post-operative observations recorded.

The focus of this study was the identification of significant post-operative complications associated with an inflammatory origin. The measured parameters were as follows, and are in keeping with the consensus on SIRS(landis 2010).

Temperature (°C)
WBC Count (mm^3)
Blood Pressure (High/Low/Normal)
ITU stay (days)
Heart Rate (High/Low/Normal)
Respiratory Rate (High/Low/Normal)
Total Hospital stay (days)

Table 12: Post-operative observations recorded.

6.2.4 Blood sampling protocol

Blood (8ml) was taken by venipuncture from all patients prior to the surgery. The blood samples were transferred from the aspiration syringe to EDTA tubes for transfer to the laboratory for processing. All samples were labelled with the patient's unique identifier and kept on ice during the transfer period, following the local safety protocols for the handling of patient blood and blood products.

6.2.5 Blood processing protocol

The blood was split into 4 aliquots and each aliquot was processed in the following manner;

Static Control	2 ml blood only
Dynamic Control	2 ml blood only
Ground DEHP plasticised PVC	2 ml blood + 0.5 gram DEHP plasticised PVC
Liquid DEHP	2 ml blood + 0.5 ml liquid DEHP

Table 13:Destination of each aliquot of patient blood. One 2ml aliquot was processed for each step as outlined above.

Once each activation well was primed with 2 ml of patient blood, the following steps were initiated.

Blood Processing Step	Description
1	Agitation at room temperature (for 30 min)
2	Remove blood (1 ml from each well in addition to the static control and dynamic control samples by using polycarbonate syringe and Eppendorf tube).
3	Separate plasma by spinning the blood in a centrifuge (13000 RPM in 10 min).
4	Transfer plasma to cryovial tubes and store at -80°C for further analysis

Table 14:Blood processing protocol performed on all patient blood samples.

Once all samples had been gathered, they were transferred from Turkey to Glasgow in dry ice and immediately transferred to -80°C upon arrival. The samples were ultimately defrosted and prepared for the two assay procedures. Three assays were carried out using the ELISA technique for the assessment of TNF-α, IL-6 and CRP and once these values had been determined and compared with the clinical outcome, FTIR assay of the molecule with the best correlation to the clinical outcomes was performed.

6.2.6 ELISA assay planning and procedure

As described earlier in chapter 4, ELISA is the standard laboratory technique for the measurement of a vast array of biomolecules. In the present study, three kits, IL-6,TNF-α and C-reactive protein molecules were purchased from (RD systems a biotechne brand, Abingdon Science Park, UK) to carry out the analysis. The company IFU's were followed for all measurements, largely as described in Chapter 4 (ELISA assay). Details of the procedures are contained in the supplier data sheets, Appendix D.

Samples distribution in the ELISA plates

As the ELISA plates have 96 wells, the first 2 columns were used for standard samples and the remaining for the patient plasma samples. Due to the number of

samples for processing, the samples were distributed to three plates of ELISA for each molecular species as outlined below.

PLATE 1

Table 15:Plasma sample distribution map for all ELISA plates.

All measurements were carried out in duplicate using spectrophotometric assay and the concentrations calculated using the reference calibration curves derived from the standard solutions.

Plate reader and standard curve

The plates were read using an Ascent spectrophotometry system (Thermo fisher scientific UK) as described in Chapter 4, section 4.5.2 of this thesis. Standard concentration were plotted for each ELISA microplate for all molecules of interest. The derived mathematical equation for the trendline curve was used for each sample measurement to derive the actual relative concentration of each sample and molecule.

6.2.7 Fourier transform infrared spectroscopy (FTIR)

Fourier transform infrared spectroscopy (FTIR) is a label-free and non-destructive technique. The technique is rapid (between 1 and 10 minutes, depending on whether the sample is wet or dry during measurement). In the present study both wet and dry measurements were taken for comparison with the ELISA data and to determine which approach provided the most accurate data.

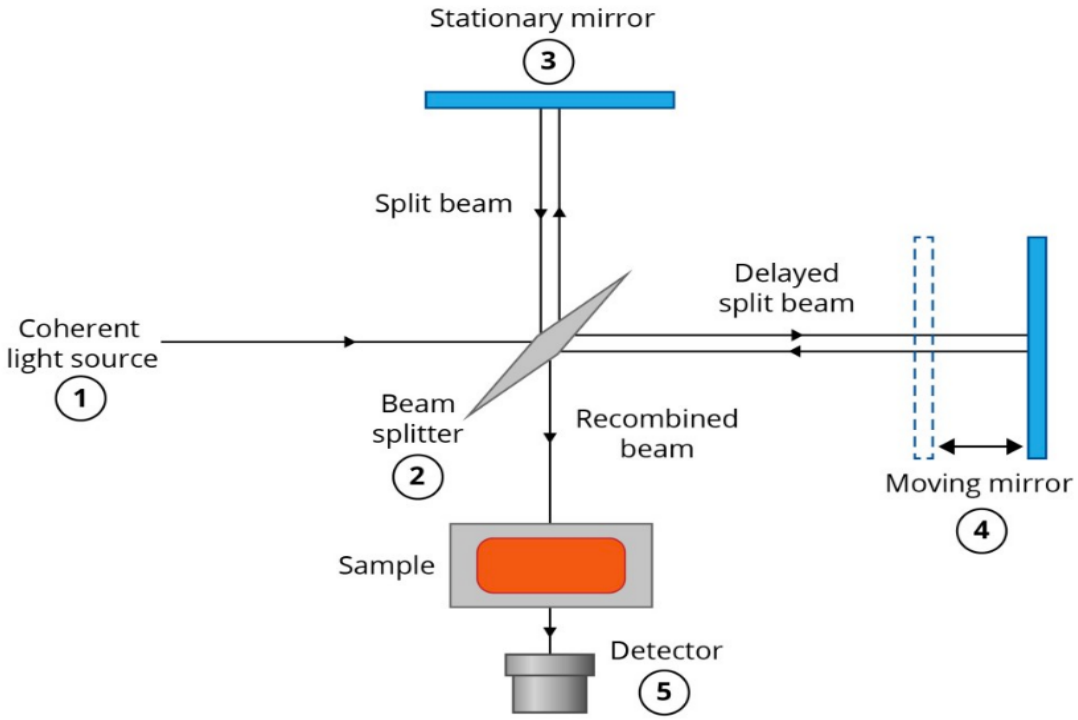

Figure 46: Fourier transform infrared technique (principle of operation).The incoming light beam from the light source is divided by the beam splitter into two beams, the first beam is reflecting from the stationary mirror whereas the second beam is reflecting from the moving mirror. Both beams are combined and pass through the sample. The results are displayed in a wide range of spectra wavelengths**. (Taken from: http://keit.co.uk/)**

Sample preparation for FTIR assessment

FTIR measurement does not require complex sample preparation. The technique can be carried out using plasma or serum samples and measurements can be performed when the sample is both wet and dry. The advantage of processing samples when wet is time related, wet samples will produce results within 1 minute, whereas dry

samples may take up to 10 minutes. The technique requires only microliters of plasma/serum, therefore analysis can be performed on very small blood samples, for example a needle stick will produce enough whole blood to carry out this assay technique.

Protocol for the work

1. Clean the diamond crystal by virkon and ethanol to ensure a clean pathway.
2. Open background page in the FITR software to allow gathering of all spectra that resulting from the sample.
3. Drop 1 microliter of the sample onto the crystal.
4. Scan to collect the wet scan wavelengths of the sample (wet scan).
5. Wait 10 minutes and rescan again (for dry scan). This step allows the water to be evaporated from the sample and increases the accuracy of the scan.

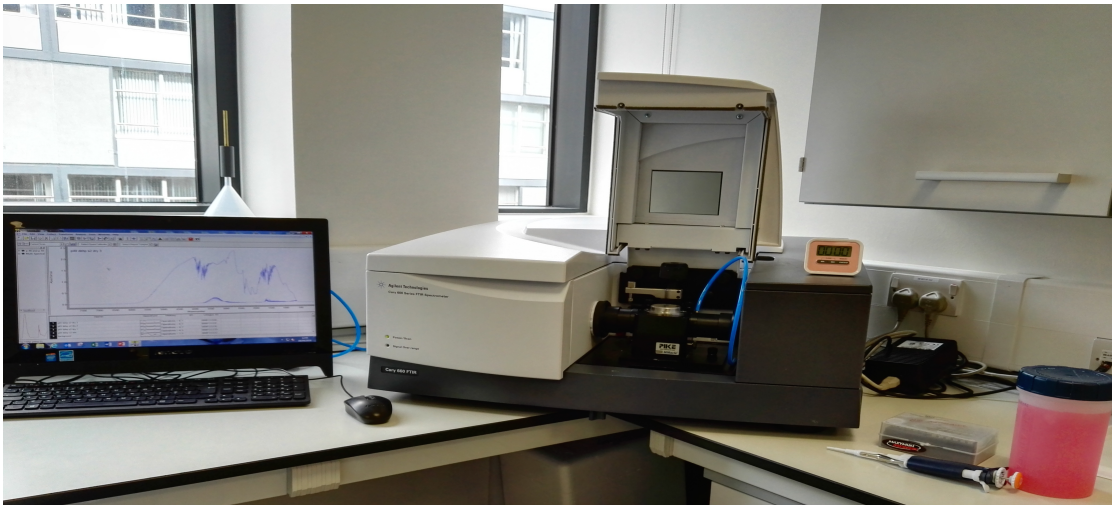

Figure 47: FTIR system employed in this study. (Fourier transform infrared spectrometer (Agilent Technology UK),Timer, Virkon disinfectant liquid). Using standard solutions, it is possible to create a concentration curve for the FTIR scans and to accurately determine the spectral component of interest.

FTIR results analysis

Patients absorbances were calculated in terms of the mean of two dry scans for two spots. MATLAB (Mathworks, USA) was used to plot all data as seen in the appendix I. Subsequently, we can specify the peak values of DEHP plasticised PVC for each patient from the data, Then, calculate the concentrations for these peaks based on the standard curve trendline equation.

The standard curve was generated based on the provided data sheet from the supplier (RD systems a biotechne brand, Abingdon Science Park, UK). Standard samples absorbances were plotted against the known IL-6 concentrations. The standard curve equation was then used to calculate IL-6 concentrations in all patients' samples.

6.3 Statistical analysis

Statistical analysis of the data, comparing measured molecular data with recorded clinical data was carried out using Minitab 17 software (Minitab Inc, Pennyslvania,USA). All patient data was divided into two groups:SIRS and non-SIRS based on the post-operative clinical observations. For the analysis of patients, data descriptive statistics were used. For continuous variables, normality tests were checked. An appropriate non – parametric test was chosen, since the data was not normally distributed. Comparisons of continuous variables between groups were applied using the Mann–Whitney ,Wilcoxon tests and t-test. A p value < 0.05 was considered statistically significant.

Regression analysis

In order to identify the sensitive inflammatory marker in blood prior to OHS, we used a binary logistic regression technique. This permits the modelling of the relationships between a dependent variable and a number of predictor variables. The

aim here was to develop a model, which can predict SIRS patients. To do this, the data was be divided into two groups: model and prediction group.

The model fit, (how well we capture the variability) was assessed using the Akaike Information Criterion (AIC) and the area under the curve (AUC): smaller AIC values indicate better models while higher AUC indicates the best model to fit the data (Akaike 1974) (Hosmer Jr and Lemeshow 2004).

AUC = 0.5	No discrimination (i.e., might as well flip a coin)
$0.7 \leq AUC < 0.8$	Acceptable discrimination
$0.8 \leq AUC < 0.9$	Excellent discrimination
$AUC \geq 0.9$	Outstanding discrimination

Table 16: Area under curve (AUC) classification.

6.4 Summary

1. The clinical study will investigate the effect of DEHP plasticised PVC and liquid DEHP on the blood samples of a cohort of patients prior to open heart surgery.
2. The response will be measured in terms of the three rapid molecules IL-6, TNF-α and CRP by using two different techniques (ELISA and FTIR).
3. A proper statistical analysis will be performed to choose the most appropriate sensitive cytokine, initiator and the best technique of measuring cytokine concentration to be used in the device development phase.

Chapter 7: Clinical study results

7 : Clincal study results

7.1 Introduction

The objectives of the clinical study are outlined in the previous chapter and revolve around determining the following factors, and are related to the destination technology that is the focus of the present study, and the sensitivity of the selected markers in identifying the propensity for inflammatory response in a population to Open-heart surgery patients;

1. What is the most appropriate initiator of the IR in isolated patient samples with the objective of deployment in a patient screening test.

2. What is the most sensitive marker of the IR in isolated patient blood samples from the molecules available to our laboratory.

3. What is the most appropriate measurement technique for markers of inflammation in isolated clinical samples.

4. What is the correlation between a heightened response to blood contact activation in an isolated patient blood sample taken prior to OHS and the indicators of IR in the post-operative period.

7.2 Patient Demographics

All 52 patients underwent open-heart surgical repair of a number of cardiac lesions. The patient demographics of this sequential group of patients is shown in table 17.

Demographical and CPB parameters	
Gender (Male/Female)	36 male and 16 female
Age (Years)	58.3 ± 11.4
Height (cm)	167.9 ± 8.8
Weight (kg)	77.5 ± 12.3
BSA (m2)	1.87 ± 0.17
Blood flow rate (L/min)	4.47 ± 0.41
Aortic cross clamping time (min)	79.38 ± 42.57
CPB time (min)	139.75± 72.05
Core temperature during the surgery (°C)	34.33 ± 3.46
Procedure	42 CABG, 5 HVR, 2 ASD, 2 AOG and 1TCA

Table 17: Summary of the basic patient demographics of the clinical study group. CABG (Coronary artery bypass graft), HVR (heart valve replacement), ASD (Arterial septal defect), AOG (ascending aorta graft), TCA(Thoracic and arcus aorta replacement). All patients' demographical data can be seen in appendix H.

As the objective of the study was to investigate a correlation between the measured cytokine response taken pre-surgery and the clinical markers of observed inflammatory response post-surgery, the clinical study also collected data relating to the observation of inflammatory processes post-surgery. These markers were discussed in the previous chapter, and the clinical observations during the post-operative period are detailed in table 18 below.

Post-operative clinical data									
P.No	Temperature (°C)	WBCs (mm^3)	Heart rate	Blood pressure	Respiratory rate	Hospital stay (Days)	ITU Stay (Days)	SIRS	Complications

28	40	13800	Normal	Normal	High	8	4	YES	ARDS
33	38	20400	High	High	Normal	9	4	YES	Died in ITU
34	36	15100	High	High	Normal	8	5	YES	liver failure

Table 19:Post-operative clinical observations with patients considered to have complications or signes of possible inflammatory SIRS. Those patients were identified based on the defined criteria by the American College of Chest/Physicians / Society of Critical Care Medicine.

The patient demographic data associated with these "complicated" patients were then extracted and compared with the “uncomplicated” patients to determine wether there were any apparent demographic factors that might influence these findings. This analysis is summarised in table 20 below.

Demographic and CPB parameters	Complicated	Uncomplicated	P
Age (years)	57.75 ± 13.7121	58.475 ± 10.8107	0.84
Height (cm)	164.5 ± 7.2425	169.025 ± 9.0340	0.73
Weight (kg)	78 ± 10.9544	77.4 ± 12.7878	0.97
Euroscore (Low ,medium and high)	1.3333 ± 0.6513	1.25 ± 0.4385	0.61
Gender	1.4166 ± 0.5149	1.275 ± 0.4522	0.36
Blood flow rate	4.4166 ± 0.356	4.4855 ± 0.427	0.91
Aortic cross clamp	111.67 ± 68.8	69.7 ± 24.859	0.62**
CPB time	194.16 ± 117.11	123.425 ± 41.66	0.63**
Temperature during the surgery	33.53 ± 5.13	34.43 ± 2.832	0.99
Operation	6 CABG, 1 ASD, 2 HVR, 2 AOG and 1 TCA	35 CABG, 3 HVR and 2 ASD	

Table 20:Comparison of patient demographic data between those patients identified with signs of an exaggerated inflammatory response to CPB and those with a normal and uncomplicated clinical course. The data are represented by mean ± Standard deviation. Unpaired t-test was perfromd to determine the signifncant differences between complicated and uncomplicated groups. CABG (coronary artery bypass graft), ASD(Arterial septal defect), AOG(Ascending aorta graft), HVR(Heart valve replacement),TCA (Thoracic and arcus aorta replacement).
**Aortic cross clamping and CPB time skewed due to one patient with highly complex and lengthy procedure (patient 33).

It was clear from this analysis that there were no statistiaclly significant differences between the patient groups in terms of the demographic factors analysed. This would suggest that there were no demographic factors that might indicate any observed inflammatory response, whether recorded prior to,or during the opertative procedure. The patient populations were similar in terms of demographics and the analysis confirmed that there were no differences between the patient groups in terms of Euroscore, a factor thought to be in some indicative of post operative complication rate.

7.3 Results of Cytokine measurement using the ELISA technique.

As described in the chapter 6, all patients underwent an activation screening test in which patient blood was exposed to both liquid DEHP and ground DEHP plasticised polyvinylchloride (DEHPPPVC). The results of these tests and the analysis process

for the 3 cytokines studied are shown in the section 7.3.1, section 7.3.2 and section 7.3.3.

7.3.1 IL-6 measurement

Standard curves were produced using standard concentrations of IL-6 supplied by the kit manufacturer. This standard curve and the associated curve equation were utilised to calculate the IL-6 concentration in each blood sample. Below is a representative IL-6 standard curve. All IL-6 standard curves can be seen in appendix E.

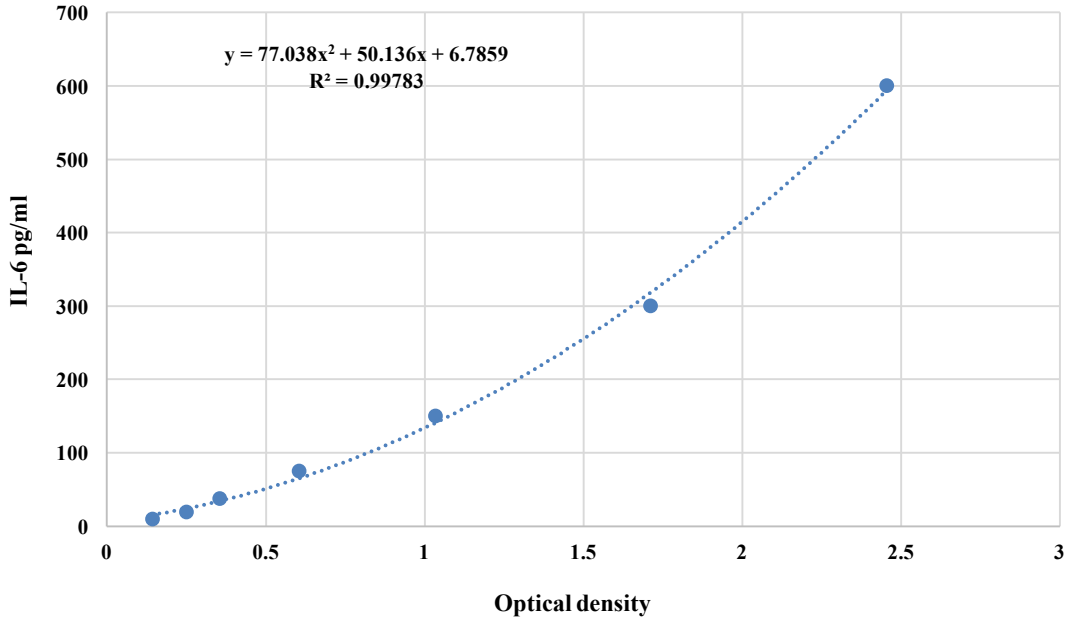

Figure 48:Representative IL-6 standard curve used in the assessment of patients' samples. Using the standard curves, the concentration of IL-6 in each blood sample was assessed post activation cycle. The results of this analysis for all 52 patients is shown in Figure 49 below.

The activation process was performed on all blood samples and in parallel both static and dynamic control samples were processed as outlined in the previous chapter. The principle behind this control measurement was to ascertain the impact of the agitation process in the expression of the cytokines of interest. In assessing the impact of the agitation, the measured cytokine value associated with the non-agitated

sample was subtracted from that of a non-exposure agitated sample. The results of this process are shown in figures 50 and 51.

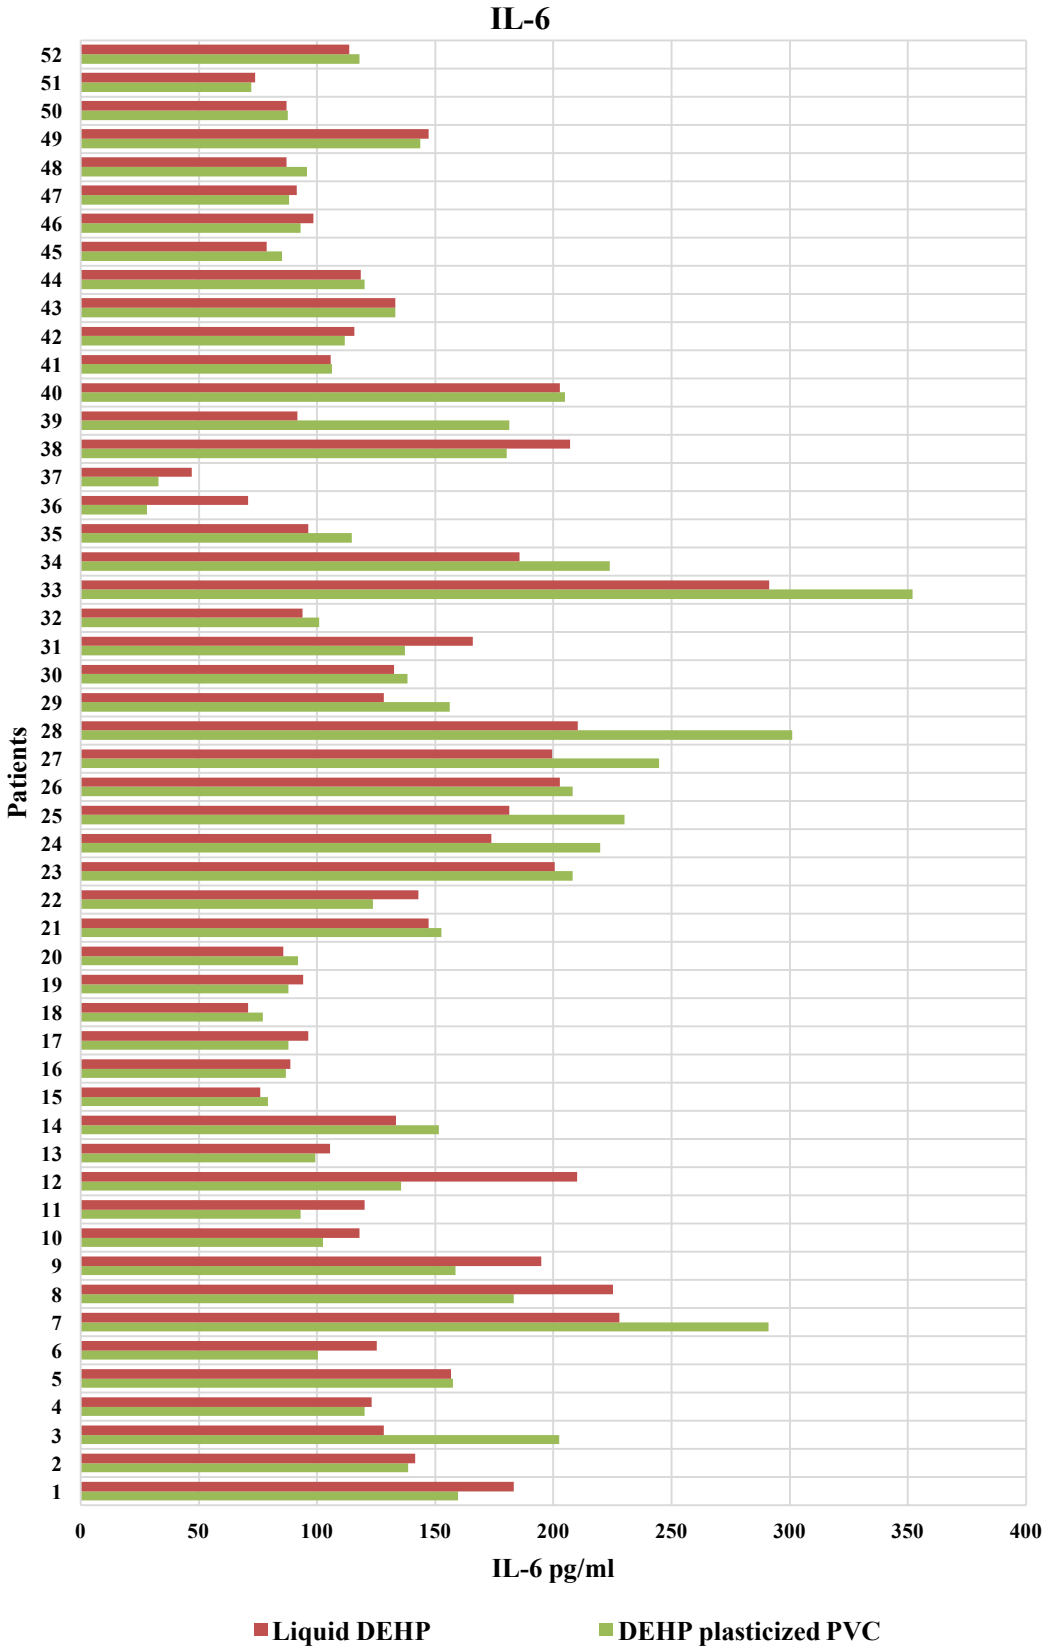

Figure 49:IL-6 measurements in pg/ml for all patients.

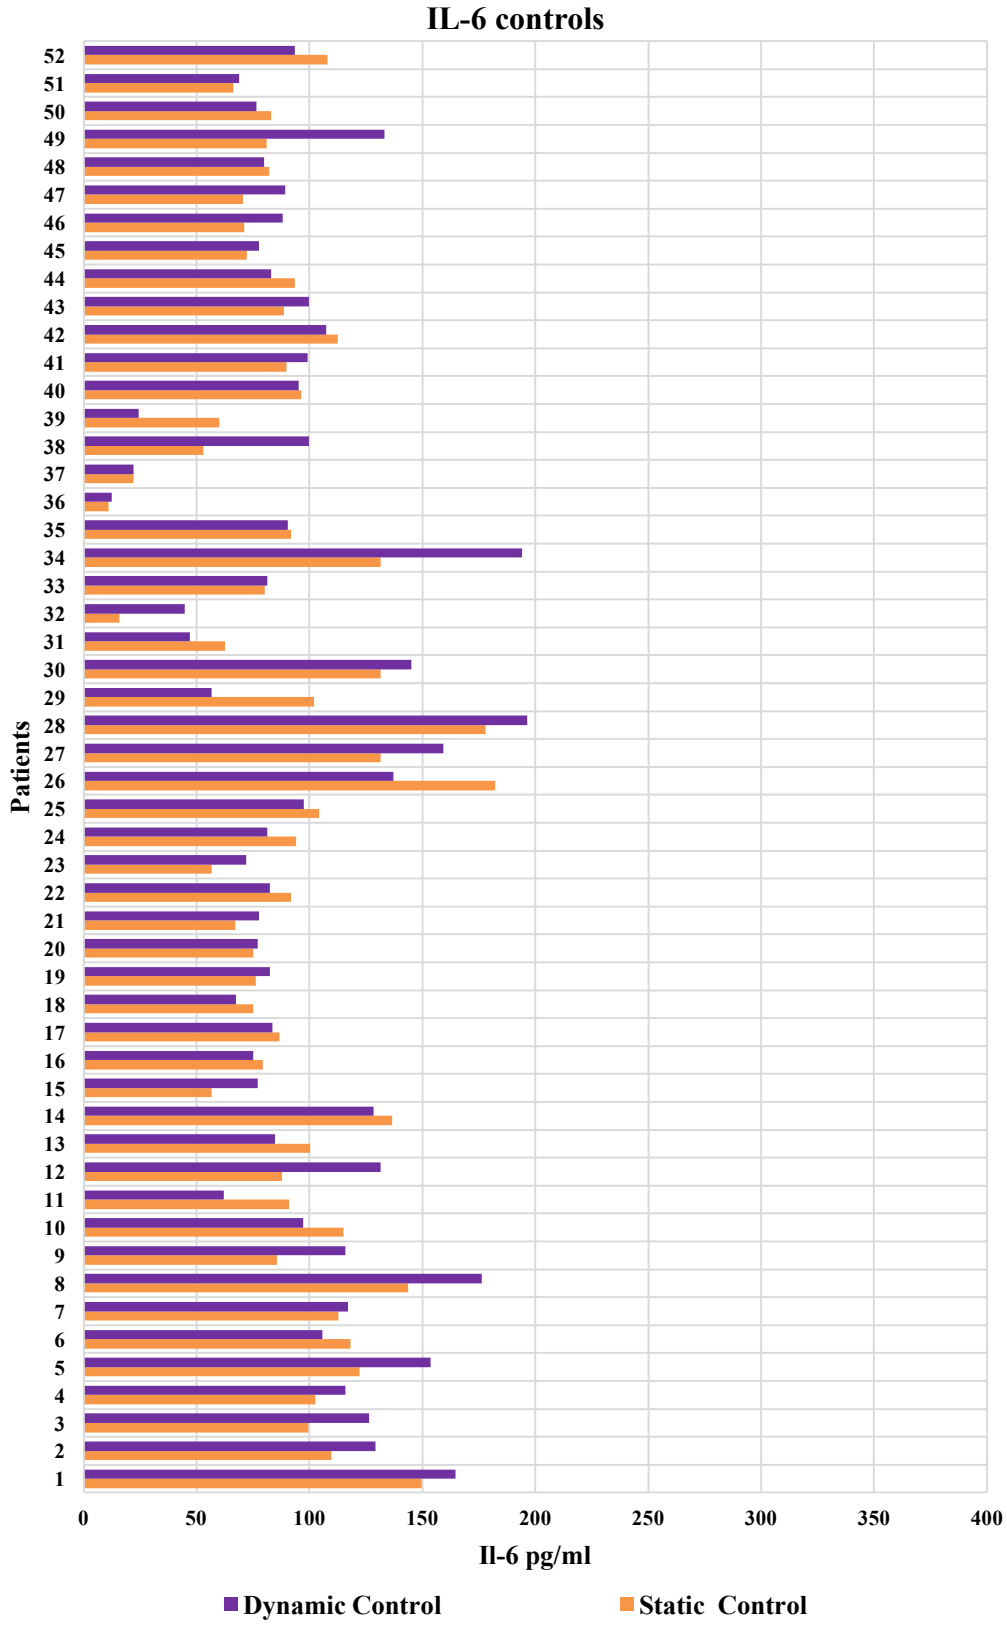

Figure 50:IL-6 Static and dynamic control values for all patients' samples.

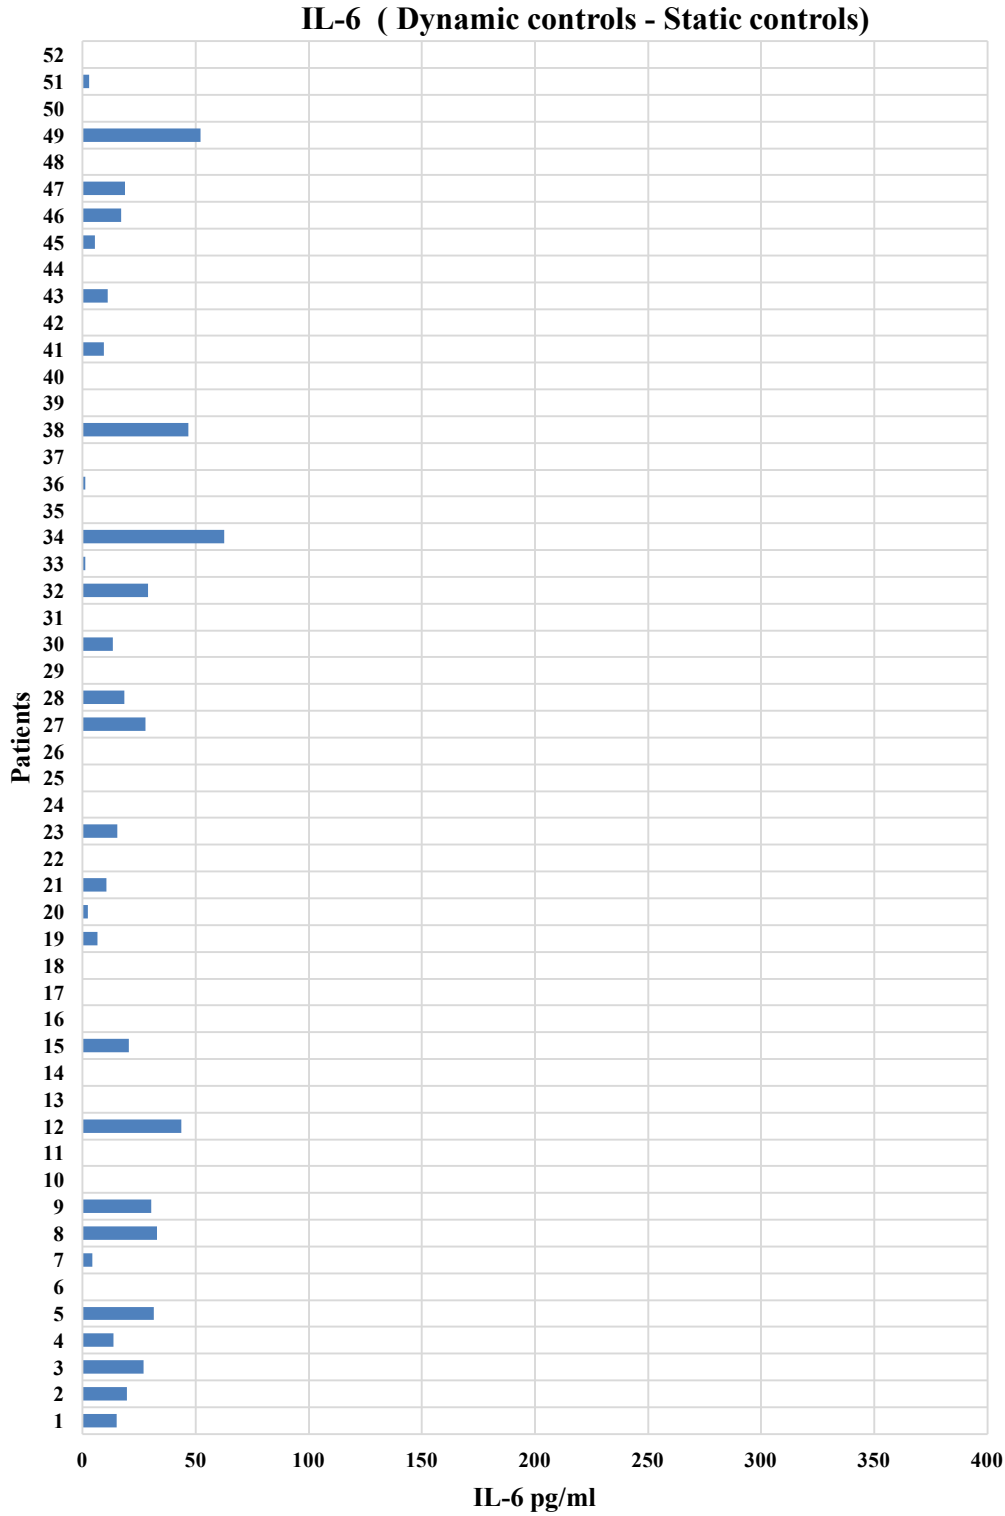

Figure 51:IL-6 (Dynamic minus static control values) for all patients. This factor is indicative of the impact of the agitation process alone on the expression of cytokines in the blood sample.

It can be seen from figures 49, 50 and 51 that there are a wide range of responses to the activation process, together with a wide ranging control response. These findings are summarized in figure 52 which shows the maximum, minimum and median values for each process and for each initiator (DEHP plasticised PVC or Liquid DEHP). The control groups showed a lower response that the exposed agitated specimens, suggesting that the exposure to the materials elicits a response.

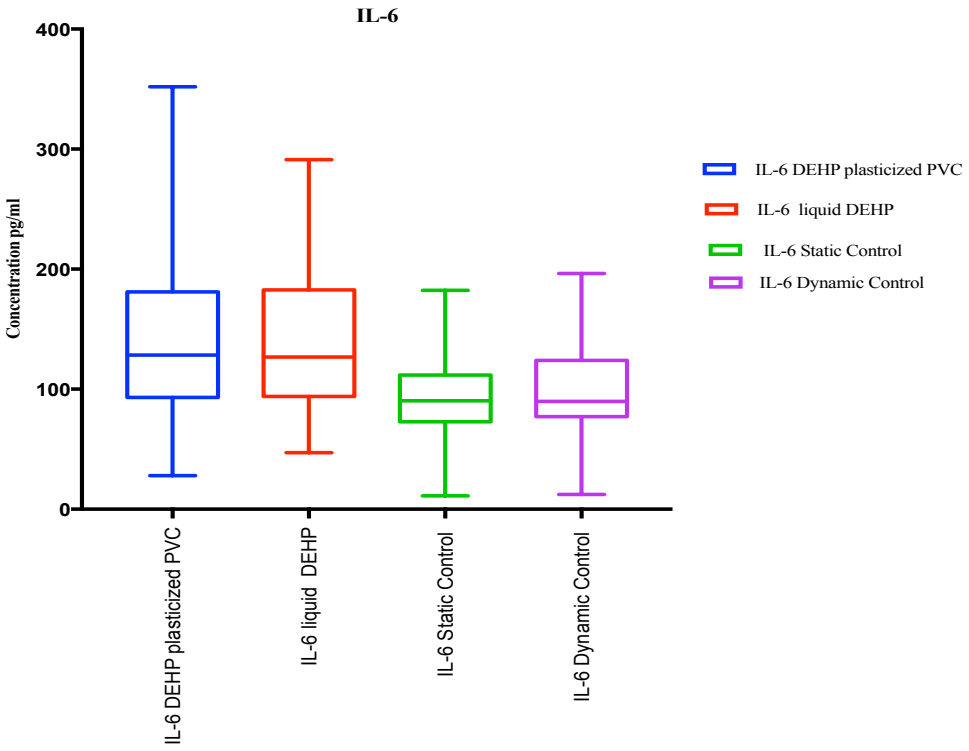

Figure 52:IL-6 maximum, minimum and median values for all patients' samples.

However, these levels require to be tested for significance and correlation with apparent systemic inflammatory response syndrome (SIRS) observations in the patient population of interest. This analysis will be demonstrated in the latter part of this chapter (section 7.5.2) by using Mann-Whitney and t-test for two sample based on the normality distribution of the data. If the p value is <0.05 the data follows non normality distribution while if p >0.05 the data follows normal distribution.

7.3.2 TNF-α measurment

Standard curves were produced using standard concentrations of TNF-α supplied by the kit manufacturer. This standard curve and the associated curve equation were utilised to calculate the TNF-α concentration in each blood sample. Below is a representaitve TNF-α standard curve. All TNF-α standard curves can be seen in appendix F.

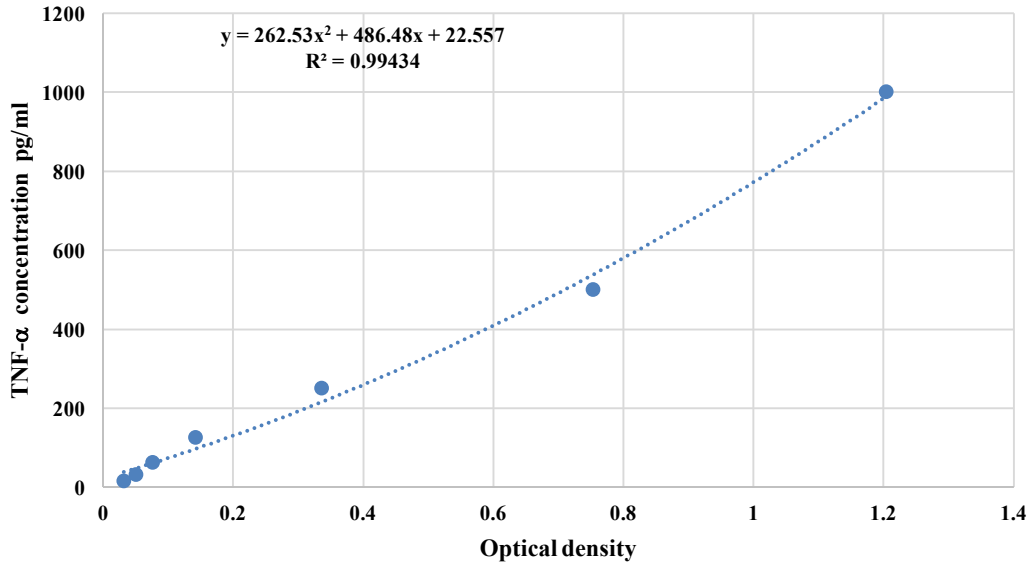

Figure 53:Representative TNF-α standard curve used in the assessment of patients' samples. Using the standard curves, the concentration of TNF-α in each blood sample was assessed post activation cycle. The results of this analysis for all 52 patients is shown in Figure 54 below.

The activation process was performed on all blood samples and in parallel both static and dynamic control samples were processed as outlined in the previous chapter. The principle behind this control measurement was to ascertain the impact of the agitation process in the expression of the cytokines of interest. In assessing the impact of the agitation, the measured cytokine value associated with the non-agitated sample was subtracted from that of a non-exposure agitated sample. The results of this process are shown in figures 55 and 56.

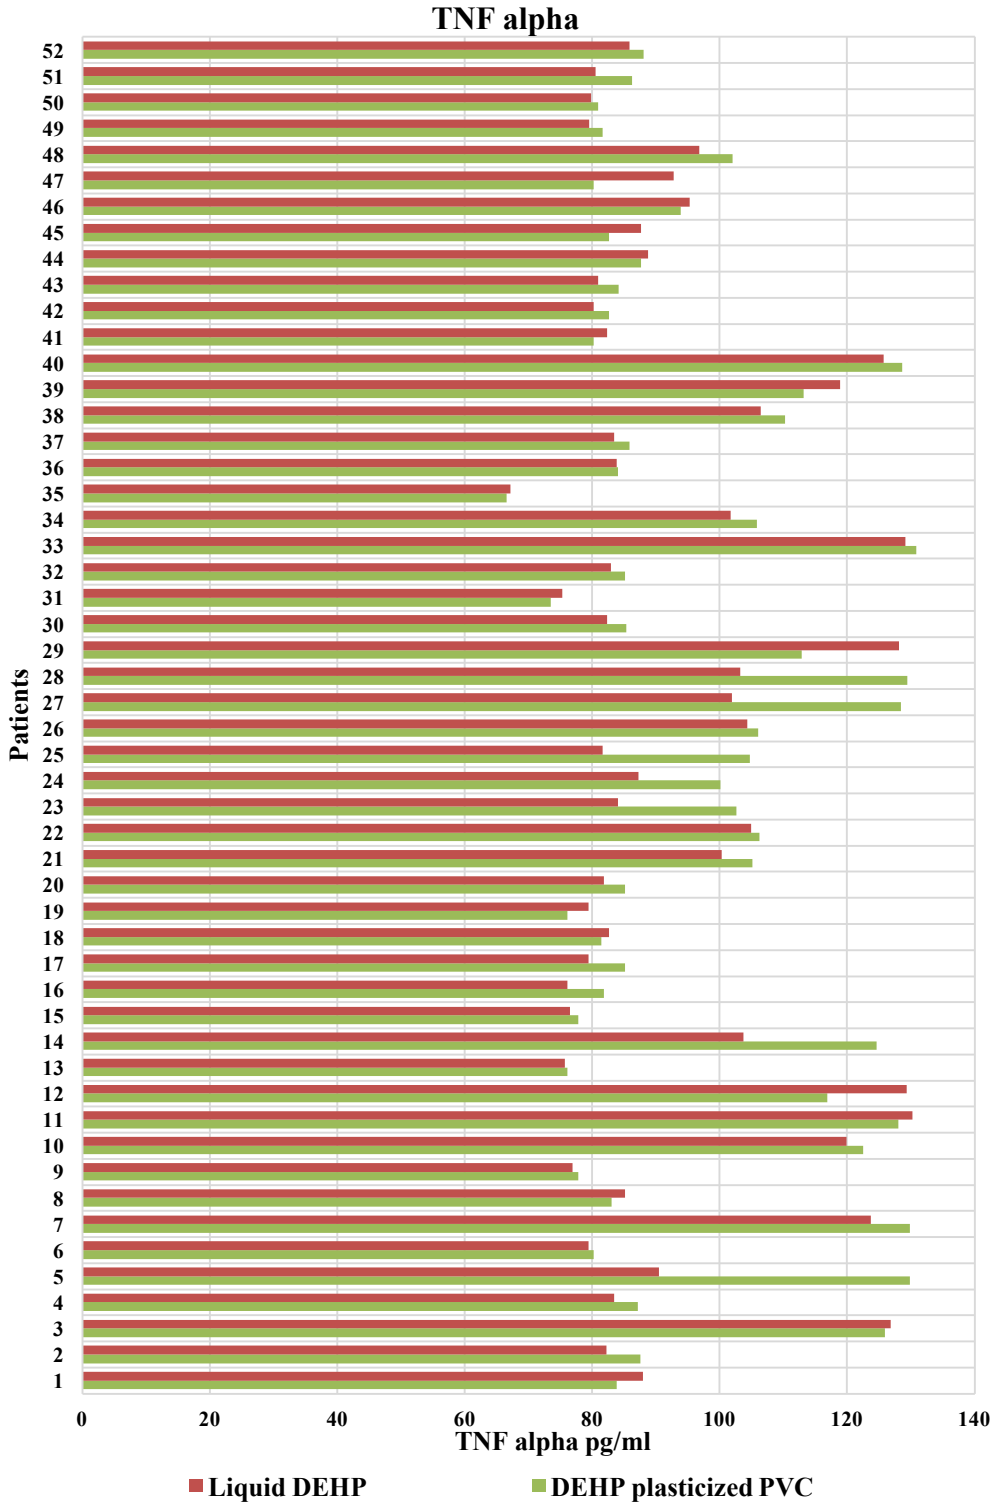

Figure 54:TNFα- measurements in pg/ml for all patients.

Figure 55:TNF-α static and dynamic control values for all patients' samples.

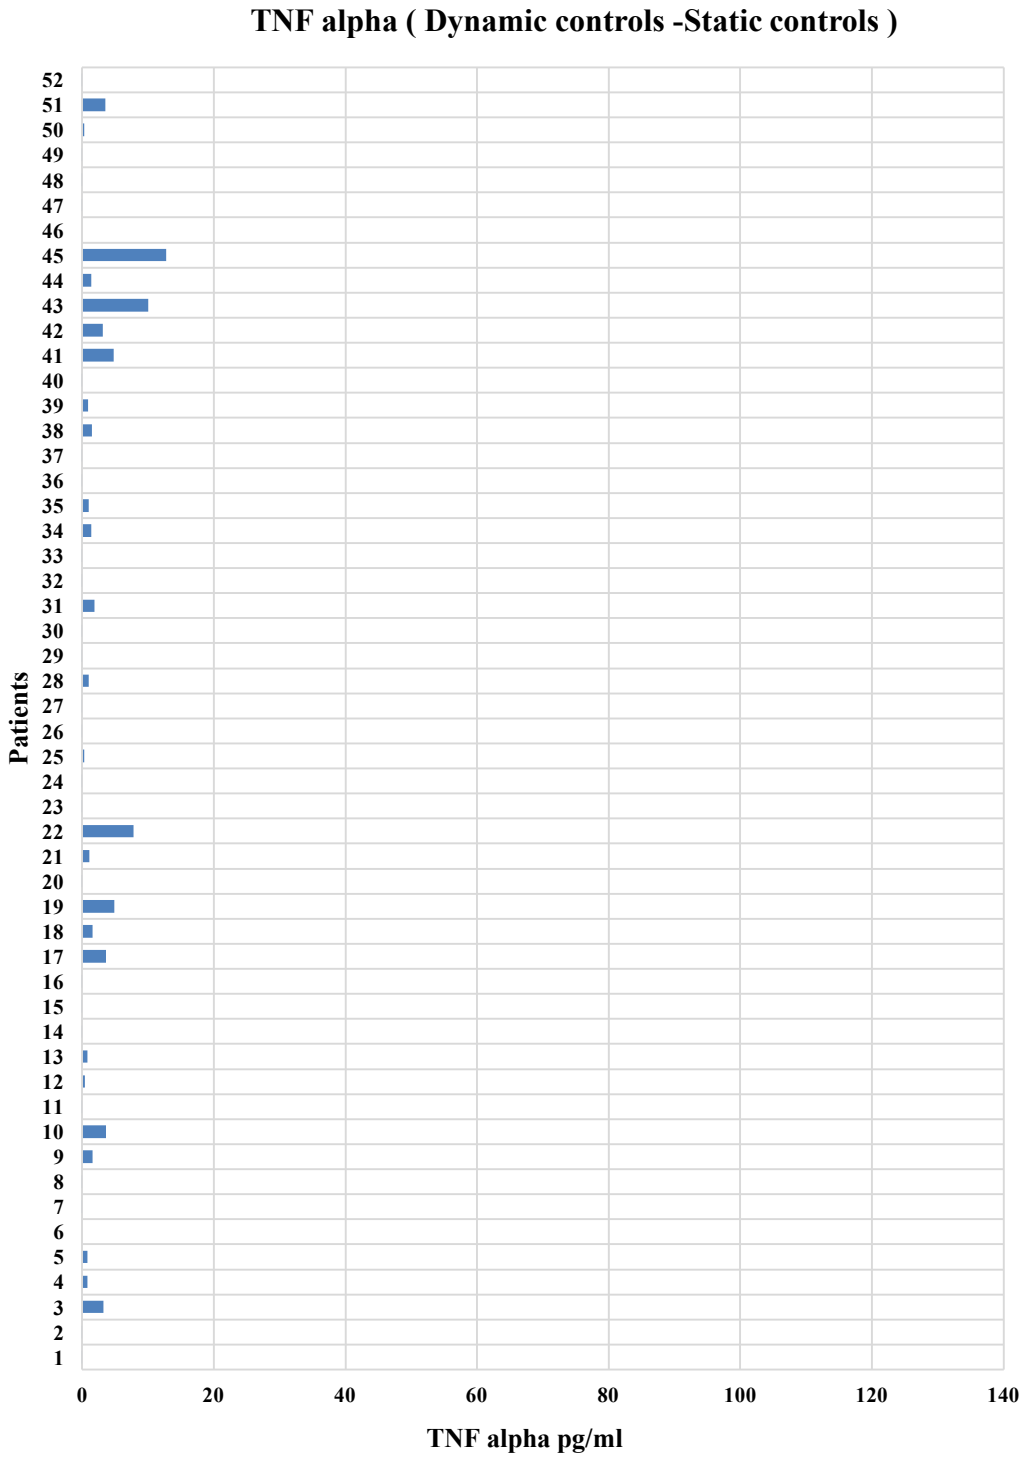

Figure 56:TNF-α(dynamic minus static control values) for all patients. This factor is indicative of the impact of the agitation process alone on the expression of cytokines in the blood sample.

It can be seen from figures 54,55 and 56 that there are a wide range of responses to the activation process, together with a wide ranging control response. These findings are summarized in figure 57 which shows the maximum, minimum and median values for each process and for each initiator (DEHP plasticised PVC or liquid DEHP). The control groups showed a lower response that the exposed agitated specimens, suggesting that the exposure to the materials elicits a response.

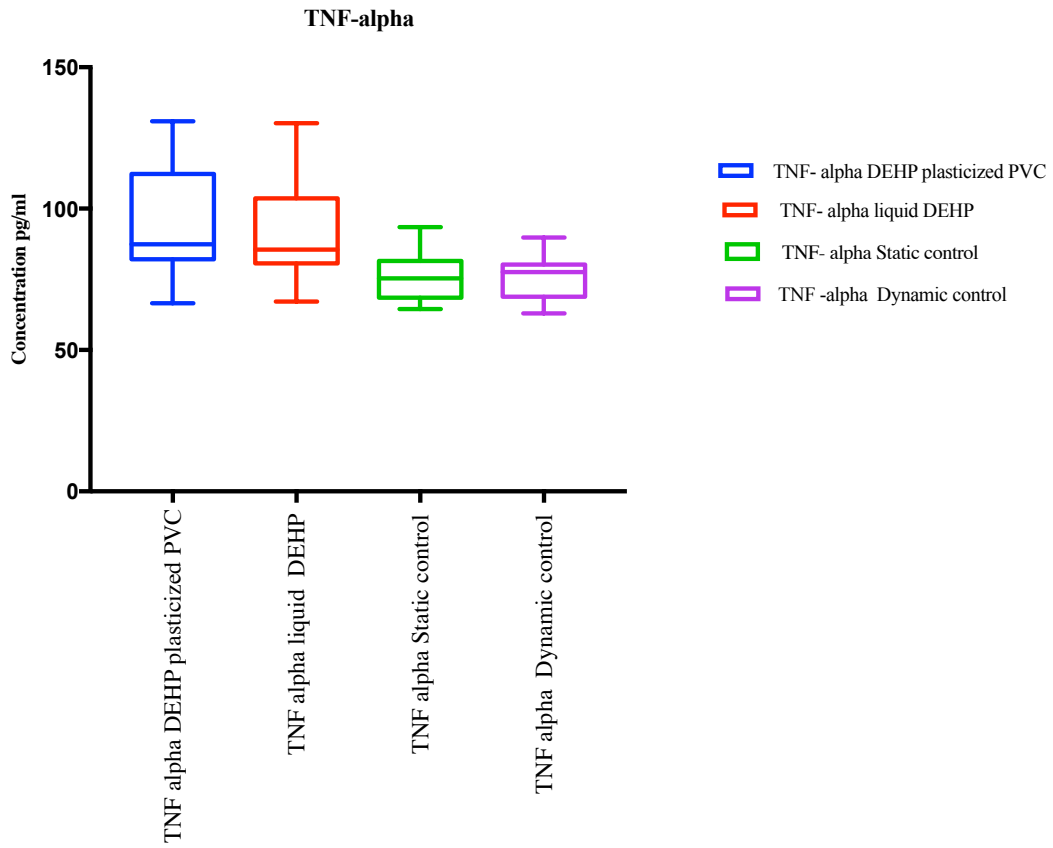

Figure 57:TNF-α minimum, maximum and median values for all patients' samples.

However, these levels require to be tested for significance and correlation with apparent systemic inflammatory response syndrome (SIRS) observations in the patient population of interest. This analysis will be demonstrated in the latter part of this chapter (section 7.5.2) by using Mann-Whitney and t-test for two sample based

on the normality distribution of the data. If the p value is <0.05 the data follows the non-normality distribution while if p >0.05 the data follows normal distribution.

7.3.3 C–reactive protein results

Standard curves were produced using standard concentrations of CRP supplied by the kit manufacturer. This standard curve and the associated curve equation were utilised to calculate the CRP concentration in each blood sample.

Below is a representative CRP standard curve. All CRP standard curves can be seen in appnedix G.

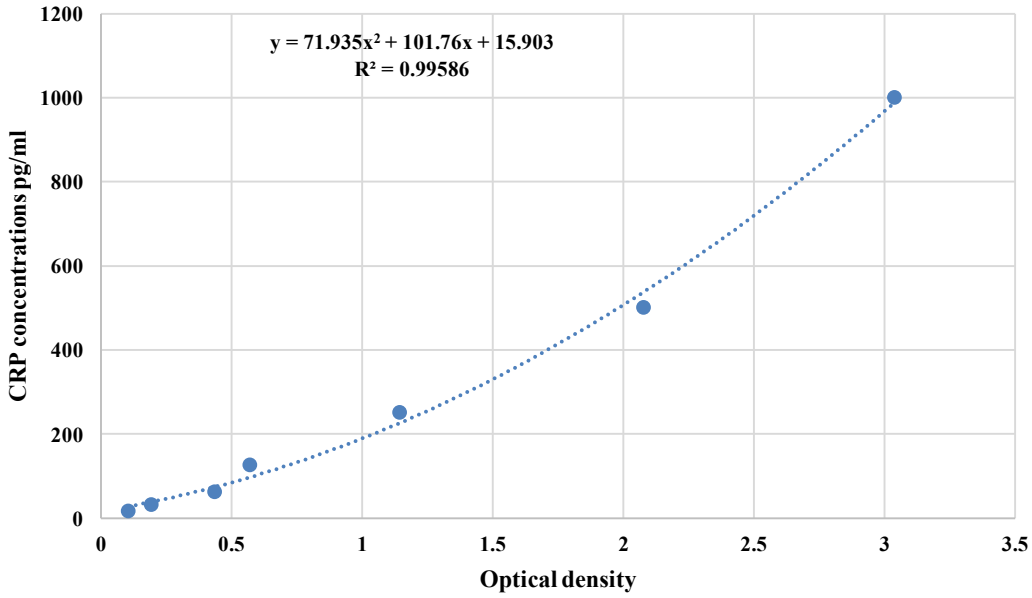

Figure 58:Representative CRP standard curve used in the assessment of patients' samples. Using the standard curves, the concentration of CRP in each blood sample was assessed post activation cycle. The results of this analysis for all 52 patients is shown in figure 59 below.

The activation process was performed on all blood samples and in parallel both static and dynamic control samples were processed as outlined in the previous chapter. The principle behind this control measurement was to ascertain the impact of the agitation process in the expression of the cytokines of interest. In assessing the impact of the agitation, the measured cytokine value associated with the non-agitated

sample was subtracted from that of a non-exposure agitated sample. The results of this process are shown in figures 60 and 61.

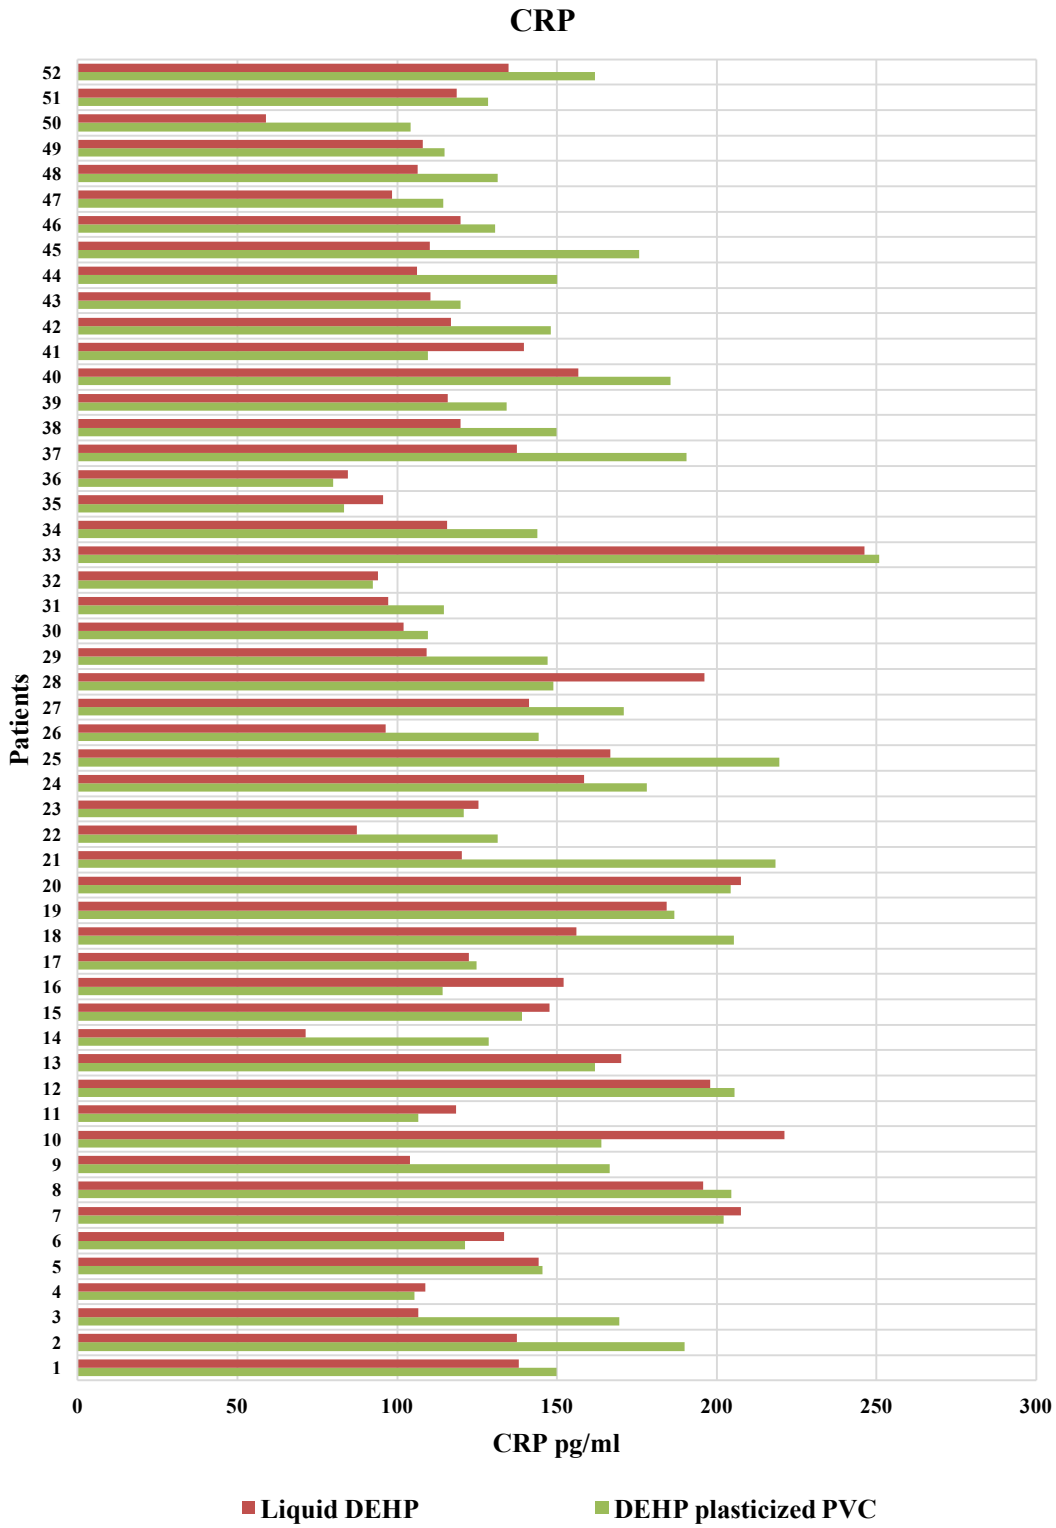

Figure 59:CRP measurements in pg/ml for all patients.

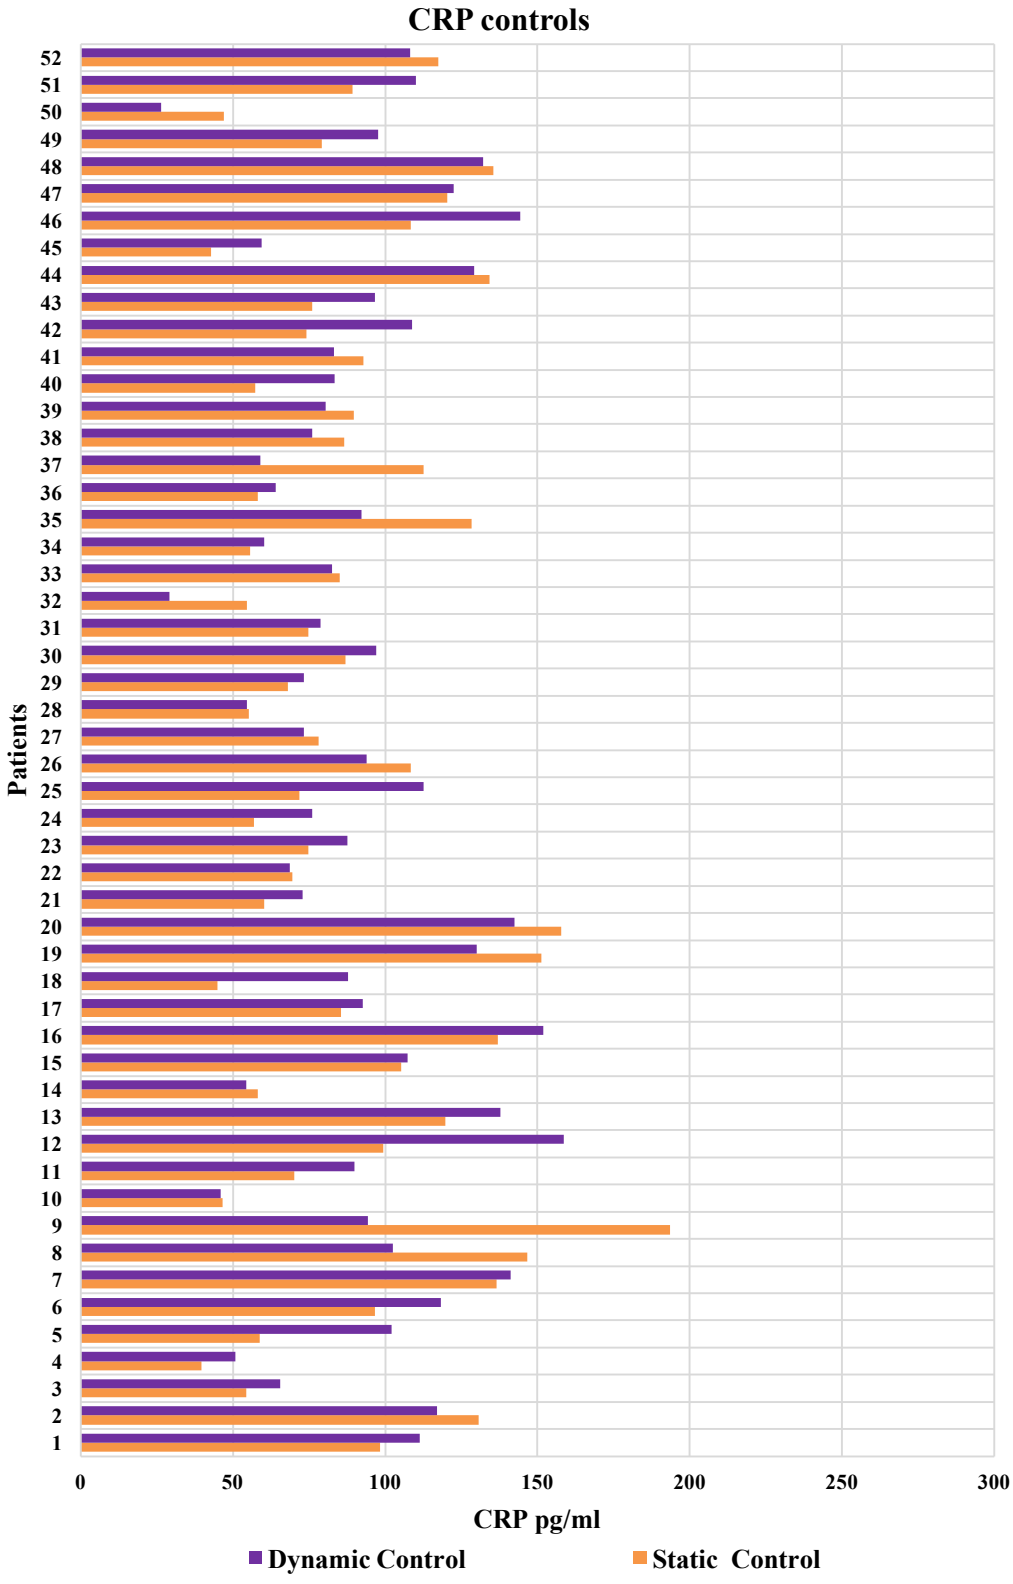

Figure 60:CRP static and dynamic control values for all patients' samples.

Figure 61:CRP (dynamic minus static control values) for all patients. This factor is indicative of the impact of the agitation process alone on the expression of cytokines in the blood sample.

It can be seen from figures 59,60 and 61 that there are a wide range of responses to the activation process, together with a wide ranging control response. These findings are summarized in figure 62 which shows the maximum, minimum and median values for each process and for each initiator (DEHP plasticised PVC or liquid DEHP). The control groups showed a lower response that the exposed agitated specimens, suggesting that the exposure to the materials elicits a response.

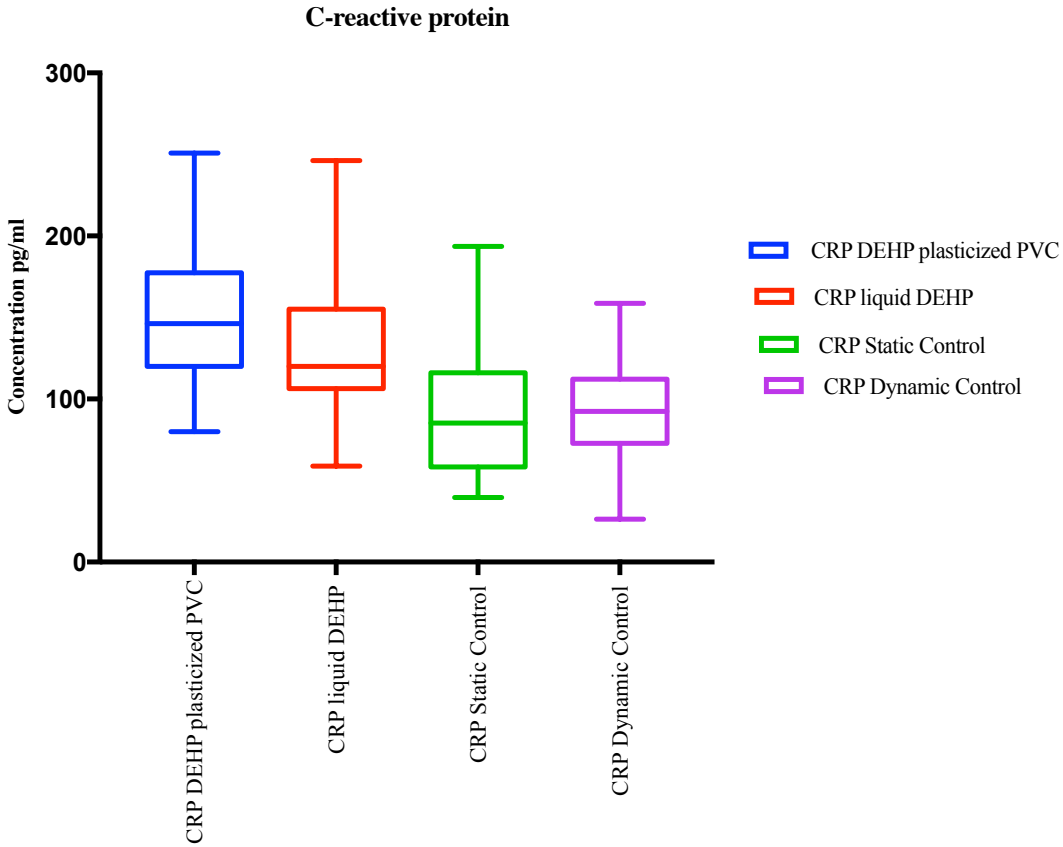

Figure 62:CRP maximum, minimum and median values for all patients' samples.

However, these levels require to be tested for significance and correlation with apparent systemic inflammatory response syndrome (SIRS) observations in the patient population of interest. This analysis will be demonstrated in the latter part of this chapter (section 7.5.2) by using Mann-Whitney and t-test for two sample based

on the normality distribution of the data. If the p value is <0.05 the data follows the non-normality distribution while if p >0.05 the data follows normal distribution.

7.4 Analysis of the accuracy of each cytokine in predicting heightened IR to the surgical procedure

The patients with known IR complications post-surgery as indicated by the battery of clinical markers have been identified .The screening process for all markers and initiators was analysed and compared to the known IR status of the patient population. These data are indicative of the most suited initiator and markers for clinical deployment and incorporation into the proposed screening technology. The result of this process is shown in table 21.Yellow color indicates the corrected predictions, green color indicates false positive and red color indicates the negative false.

Patients numbers	SIRS (Y/N)	IL-6 DEHP plasticized PVC >190 pg /ml	IL-6 liquid DEHP >190 pg/ml	TNF-alpha DEHP plasticized PVC>90 pg/ml	TNF-alpha liquid DEHP>90 pg/ml	CRP DEHP plasticized PVC > 190 pg/ml	CRP liquid DEHP > 190 pg/ml

Table 21:Comparison of known IR status in the patient population with the assay results for all configurations of initiator and marker. The table describes conforming results, false positive results (green) and false negative results (red) for all configurations.

In normal clinical practice, clinicians utilize a number of predictive scoring systems to determine the level of risk a particular patient has for the surgical procedure. The most commonly used scoring system in cardiac surgery is the EuroScore ('European System for Cardiac Operative Risk Evaluation').The basis of this scoring system is an analysis of a range of risk factors and patient specific and lifestyle measures to assess the risk of mortality and morbidity associated with cardiac surgery. The process returns a EuroScore number from 1-6, but clinicians often report this as Low, Medium and High risk. In the context of the present study, we considered a EuroScore in the Medium and High categories as indicative of possible post-operative complications. The high category was considered separately as a possible more subtle indicator of complications. The result of this process is shown in table 22 below.

These data confirm that the EuroScore pre-clinical assessment bears no significant correlation with the clinical outcome in terms of complications associated with SIRS. The EuroScore predicted only 25% of the SIRS complicated patients correctly, and was associated with 10 false positive predictions and 21 false negative complications. We surmise from this process that the Euroscore is not a good predictor of SIRS complicated outcomes.

Table 22: Analysis of Euroscore as an identifier of post-operative complications of inflammatory origin.The data shows quite clearly that the EuroScore is ineffective in this regard, with a correlation with outcome of only 25% and 10 false positives, 21 false negatives.

The data derived from the assessment of cytokine screening pre-operatively are further analysed in table 23 and the apparent best fit configuration is derived from the combination of conforming results and the minimum number of false positives and negatives.

Predictors	Prediction percentage	False positive	False negative
IL-6 DEHP plasticised PVC	66.70%	3	3
IL-6 liquid DEHP	50%	5	6
TNF-alpha DEHP plasticised PVC	83.30%	13	2
TNF-alpha liquid DEHP	75%	12	4
CRP DEHP plasticised PVC	41.60%	4	7
CRP liquid DEHP	50%	1	6

Table 23:Analysis of the predictive capability of all configurations of markers and initiators. The objective is to determine the most accurate marker/initiator configuration in terms of conforming results and false values.

These data suggest that the combination of IL-6 and DEHP plasticised PVC has the best overall predictive potential. This combination resulted in the identification of 66.7% (8 out of the 12 confirmed IR patients) and only 6 false positives out of the 40 non IR patients (13%). TNF-α in combination with both initiators had the best predictive quality in terms of the confirmed patients (83.3% DEHP plasticised PVC, 75% Liquid DEHP), but both were associated with a much higher degree of false readings in the non-IR population (37% and 40% respectively). The CRP results did not produce particularly promising results in terms of the predictive qualities of either configuration.

These findings will be tested statistically in section 7.5.

7.5 Statistical analysis

7.5.1 Association between control samples (static and dynamic) and samples with both initiators (DEHP plasticised PVC and liquid DEHP)

Before analyzing the patient screening data in terms of statistically significant predictive qualities, it is important to assess whether, when compared to static and dynamic control values, there is a significant activation of the various cytokines associated with contact with the two initiators (liquid DEHP and DEHP plasticised PVC). A one sample Wilcoxon test was performed to both IL-6 DEHP plasticised PVC and IL-6 DEHP scores. The results showed a positive association between the IL-6 DEHP plasticised PVC and IL-6 DEHP with both static and dynamic control groups as seen in the below table 24. DEHP plasticised PVC lead to increase the IL-6 levels approximately 43 times when compared to static and dynamic control groups. Liquid DEHP followed the same pattern by increasing the concentration 35 times which confirms the role of both initiators in the elevations levels of IL-6. Moreover, from the confidence interval, it can be reported that 95% confidence there are significant effect of PVC and DEHP in the elevation of IL-6 concentrations.

Test	Median	95%CI
IL-6 DEHP plasticised PVC -SC	43. 1	(23.3, 62.6)
IL-6 DEHP plasticised PVC-DC	35.6	(17.5, 53.3)
IL-6 liquid DEHP-SC	38.3	(24.8, 53.6)
IL-6 liquid DEHP-DC	35	(19.8, 46.7)

Table 24:Wilcoxon test for IL-6 patients results.IL-6 scores for all patients with both initiators (Plasticised PVC and liquid DEHP) were subtracted from the control scores in order to determine the effect of these initiators in terms of the overexpression of IL-6 levels.

A similar analysis was carried out on the TNF-α data using static, dynamic and Liquid DEHP and PVC results. The results in table 25 show the effect of initiators in TNF-α levels. These data confirm that, when compared to the IL-6 results, TNF-α

produces a less significant effect. As can be seen TNF-α with DEHP plasticised PVC reported an increase by 20.6 times while IL-6 with DEHP plasticised PVC increase the concentration by 40 times, suggesting a stonger activation effect.

Test	Median	95%CI
TNF-α DEHP plasticised PVC-SC	20.6	(13.4, 25.5)
TNF-α DEHP plasticised PVC-DC	20.2	(13.6, 25.5)
TNF-α liquid DEHP-SC	15	(10.4, 21.5)
TNF-α liquid DEHP-DC	14.6	(10.1, 21.7)

Table 25:Wilcoxon tests for TNF-α patients results. TNF-α scores for all patients with both initiators (Plasticised PVC and liquid DEHP) were subtracted from the control scores in order to determine the effect of these initiators in terms of the overexpression of TNF-α levels.

From the CRP results, it can be summarized that both initiators DEHP plasticised PVC and liquid DEHP lead to increased CRP levels with varying response across the patient group. By performing the Wilcoxon test, seen in table 26, it can be seen that there is a strong effect of both initiators in increasing CRP levels.

Test	Median	95%CI
CRP DEHP plasticised PVC-SC	56.7	(44.1, 71.8)
CRP DEHP plasticised PVC-DC	55.7	(43.4, 68.3)
CRP liquid DEHP-SC	40.3	(30.9, 52.1)
CRP liquid DEHP-DC	36.4	(27.0, 46.4)

Table 26:Wilcoxon test for CRP patients' results . CRP scores for all patients with both initiators (Plasticised PVC and liquid DEHP) were subtracted from the control scores in order to determine the effect of these initiators in terms of the overexpression of CRP levels.

7.5.2 Determine the difference between clinically observed SIRS and NON SIRS in terms of the cytokine levels

All patient ELISA data were entered into a Minitab worksheet and then separated into two groups (SIRS groups and non-SIRS groups) based on the post-operative clinical data. A Mann-Whitney and/or t-test was performed on the data based on its normality distribution. This analysis is shown in the below figures (63, 64, 65, 66, 67 and 68).

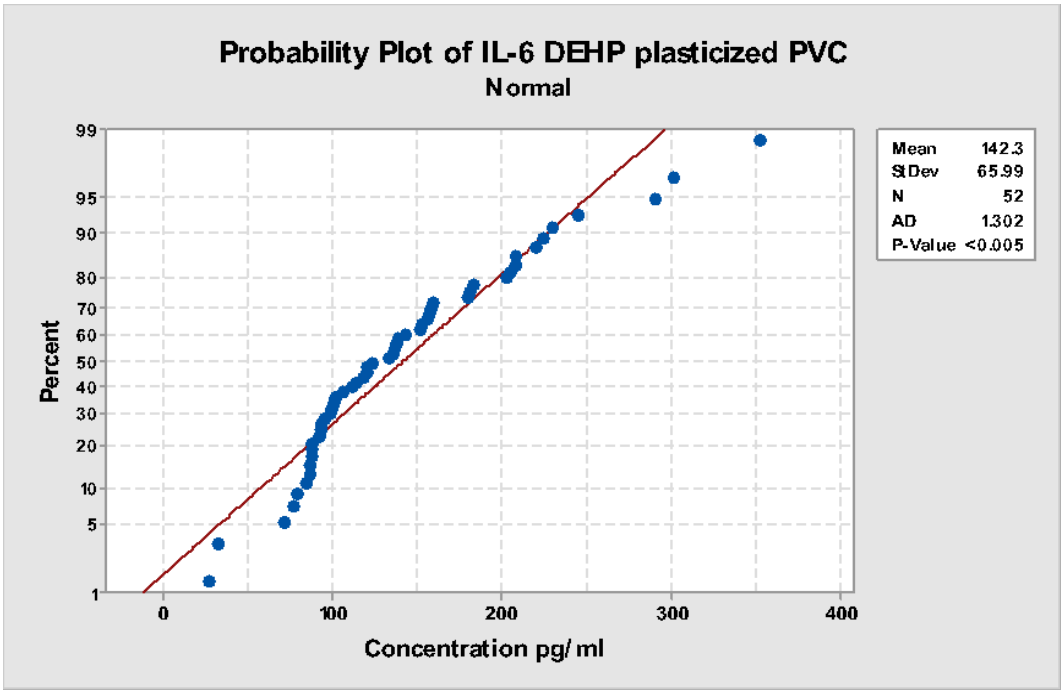

Figure 63:IL-6 DEHP plasticised PVC normality distribution ($p<0.05$)

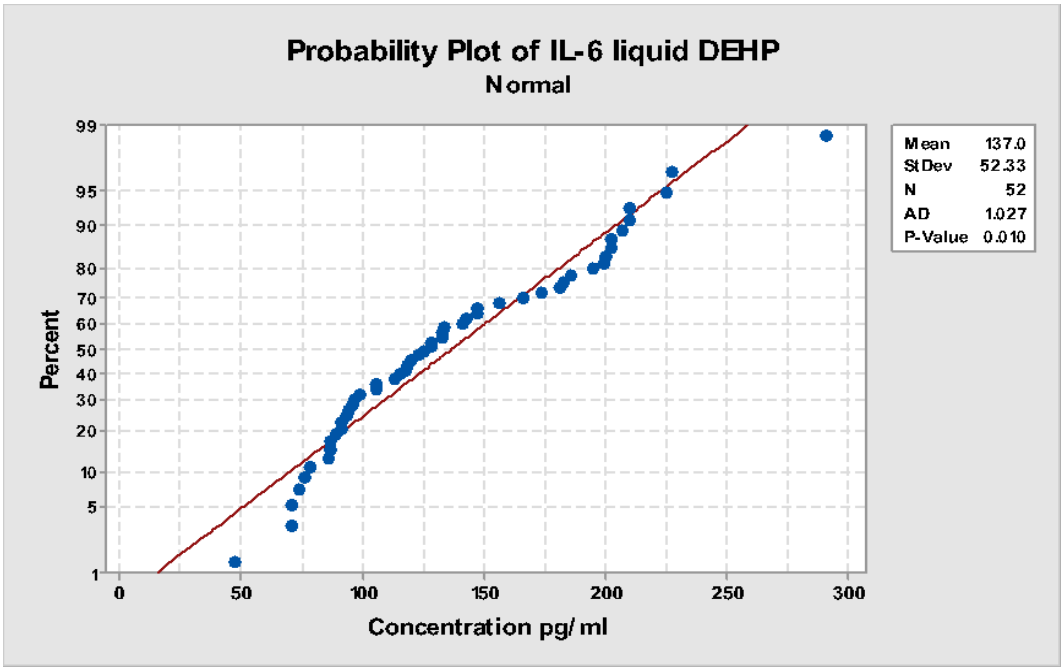

Figure 64:IL-6 liquid DEHP normality distribution ($p<0.05$)

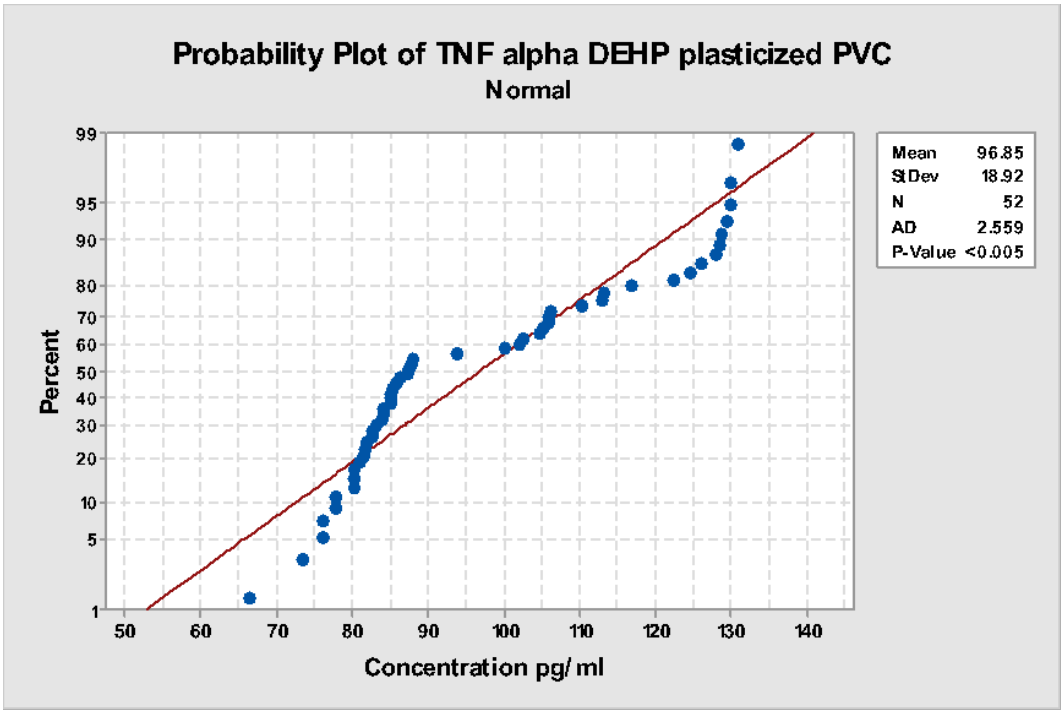

Figure 65:TNF-α DEHP plasticised PVC normality distribution (p<0.005)

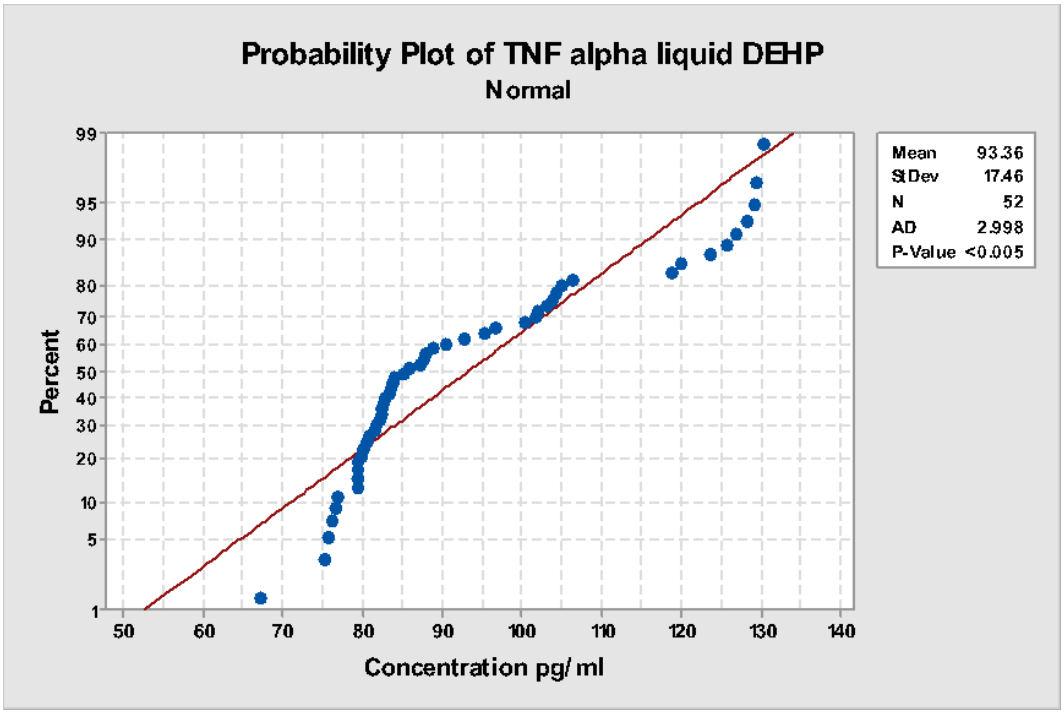

Figure 66:TNF-α liquid DEHP normality distribution(p<0.005)

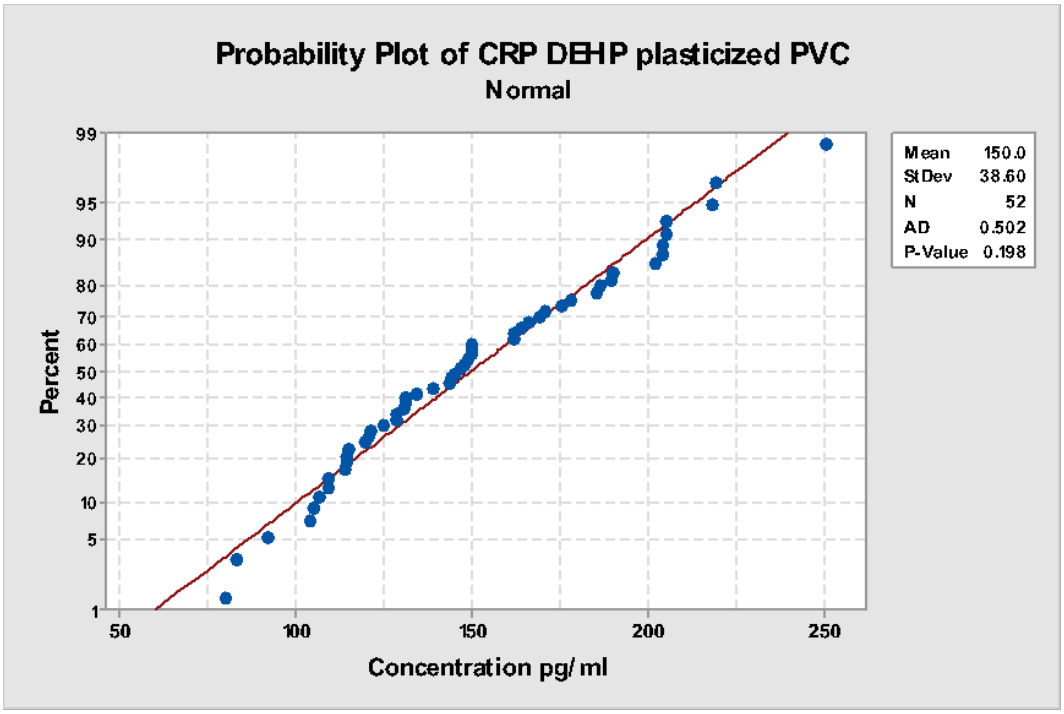

Figure 67:CRP DEHP plasticised PVC normality distribution (p=0.198)

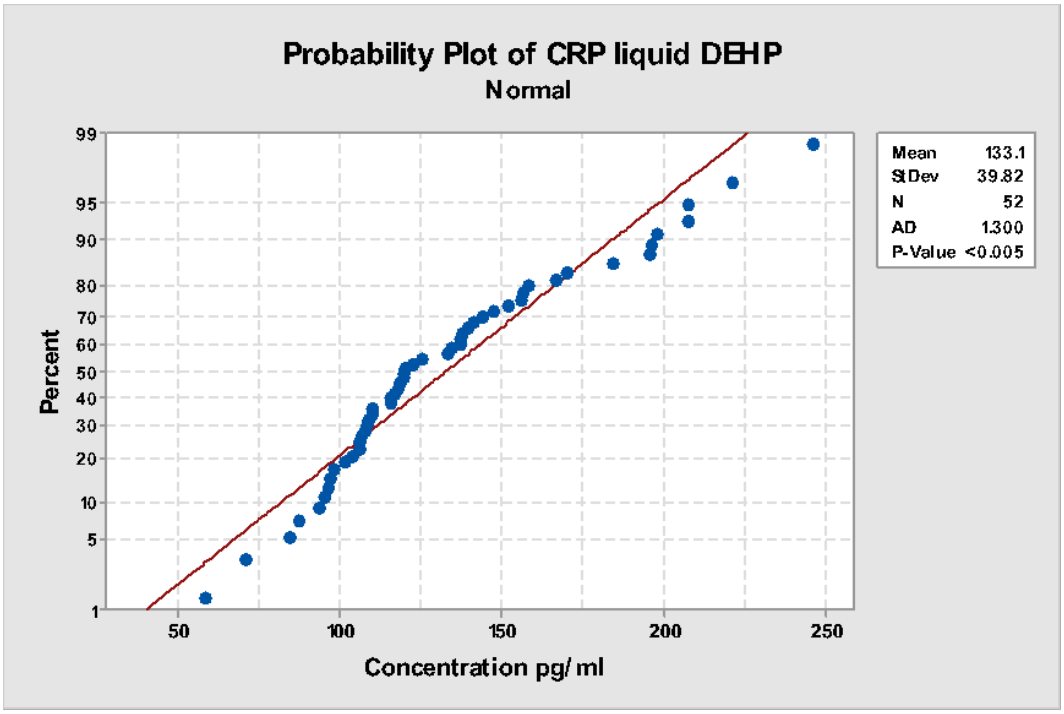

Figure 68:CRP liquid DEHP normality distribution(p<0.005).

The normality distribution analysis showed that all data followed a non-normal distribution with p<0.005 except CRP DEHP plasticised PVC that had p>0.05 which

is considered to be normal. Therefore a conventional two sample t-test was performed for CRP DEHP plasticised PVC on both SIRS and non-SIRS groups while Mann-Whitney test performed on IL-6 DEHP plasticised PVC ,IL-6 liquid DEHP, TNF-α DEHP plasticised PVC,TNF-α liquid DEHP ,CRP liquid DEHP with SIRS and non-SIRS patients. The results of this analysis are shown in table 27 below.

Test	SIRS	NON -SIRS	CI	P
Mann-Whitney Test and CI: IL-6 DEHP plasticised PVC SIRS, IL-6 DEHP plasticised PVC NON- SIRS	Median =221.82	Median=116.28	(48.71,138.16)	0.0002
Mann-Whitney Test and CI: IL-6 liquid DEHP SIRS, IL-6 liquid DEHP NON -SIRS	Median =192.57	Median= 117.13	(32.07,101.02)	0.0005
Mann-Whitney Test and CI: TNF-α DEHP plasticised PVC SIRS, TNF-α DEHP plasticised PVC NON –SIRS	Median =119.69	Median = 85.23	(10.63,39.12)	0.0046
Mann-Whitney Test and CI: TNF-α liquid DEHP SIRS, TNF-α liquid DEHP NON – SIRS	Median =102.61	Median= 83.46	(2.20,31.13)	0.0196
Two-Sample T-Test and CI: CRP DEHP plasticised PVC SIRS, CRP DEHP plasticised PVC NON –SIRS	Mean=185	Mean=139.5	(23.2, 67.8)	0.0003
Mann-Whitney Test and CI: CRP liquid DEHP SIRS, CRP liquid DEHP NON- SIRS	Median=182.98	Median= 117.57	(33.23,85.70)	0.0002

Table 27:Significance test for IL-6,TNF-α and CRP on SIRS and non-SIRS patients.

The above table confirmed that IL-6, TNF-α and CRP can be used as a predictor for SIRS based on the significance difference between the two groups ($p<0.05$) and 95 confidences in both arms of the study interval support this assertion.

7.5.3 Regression analysis to specify the best model that can be used as a predictor of SIRS

We carried out a binary logistic regression to investigate the relationship between response variables and predictors. The analysis was performed using 6 variables; IL-6 DEHP plasticised PVC; IL-6 liquid DEHP;TNF-α DEHP plasticised PVC; TNF-α liquid DEHP ; CRP DEHP plasticised PVC; CRP liquid DEHP. The response is SIRS which equates to either a yes or no response. Both AIC and AUC can predict the best fit model of the data. Other indicators of the fit of the model will also be tested, including, predictive power and goodness of fit tests (deviance, Pearson and Hosmer- Lemeshow).

Method

The patients were randomly separated into two groups, a regression group and a predicted group, in a ratio in the order of 2:1 respectively (Hosmer Jr and Lemeshow 2004).The sensitivity and specificity of the test is crucial in specifying the SIRS patients, achieved by determining the probability cut off value (p cut off).The resultant Reciever Operating Curve, sensitivity (true positive, known SIRS patients) v 1-specificity (false positive, non-SIRS patients). To select p cut off value, high sensitivity and high specificity probabilities will be specified from the probabilities values. To determine the sensitivity only the highest values of each assay were employed. High sensitivity indicates that only true SIRS patients are named as SIRS while high specificity means non-SIRS patients are named as SIRS. Therefore, according to the ROC structure, X axis is presenting the values of 1-specificity. Hence, we need to select the high specificity value to lower the values of false positive and achieve the best cut off value. In analysing this data, the AUC of each plot is calculated and the higher value suggests the best fit model.

Model 1: IL-6 DEHP plasticised PVC

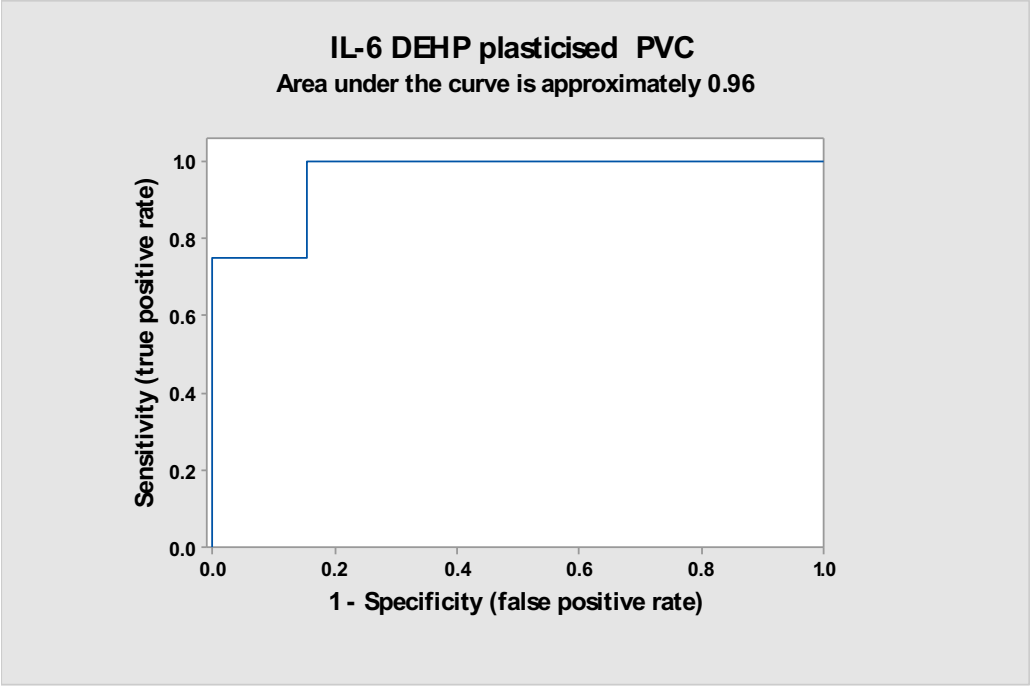

Figure 69:IL-6 DEHP Plasticised PVC model.

Model 2: IL-6 liquid DEHP

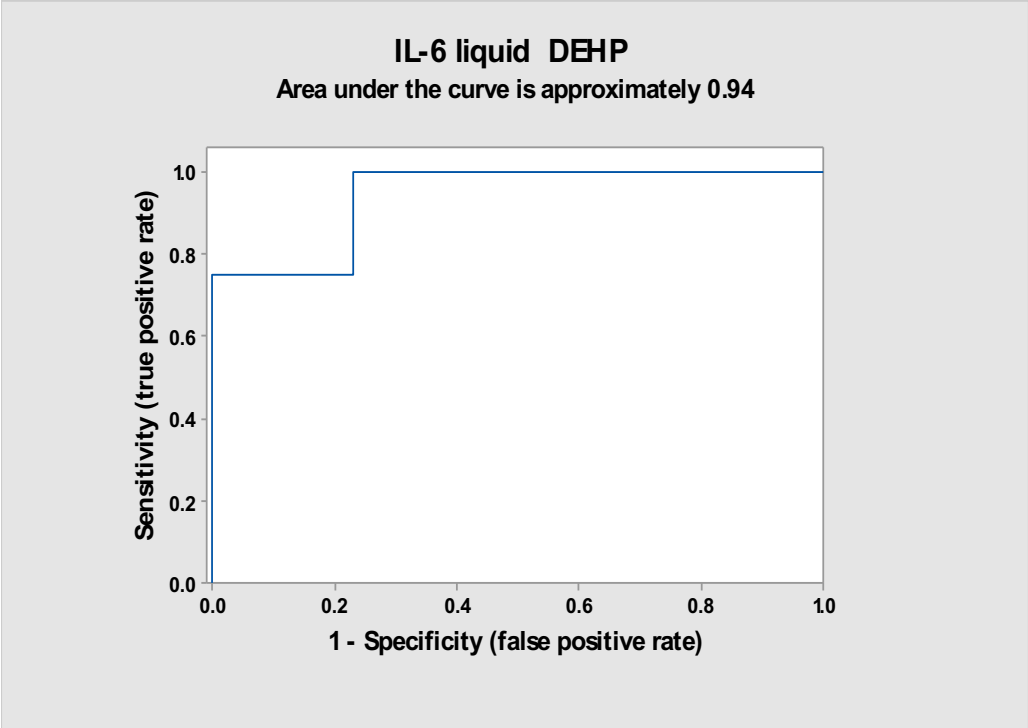

Figure 70:IL-6 liquid DEHP model.

Model 3: TNF-α DEHP plasticised PVC

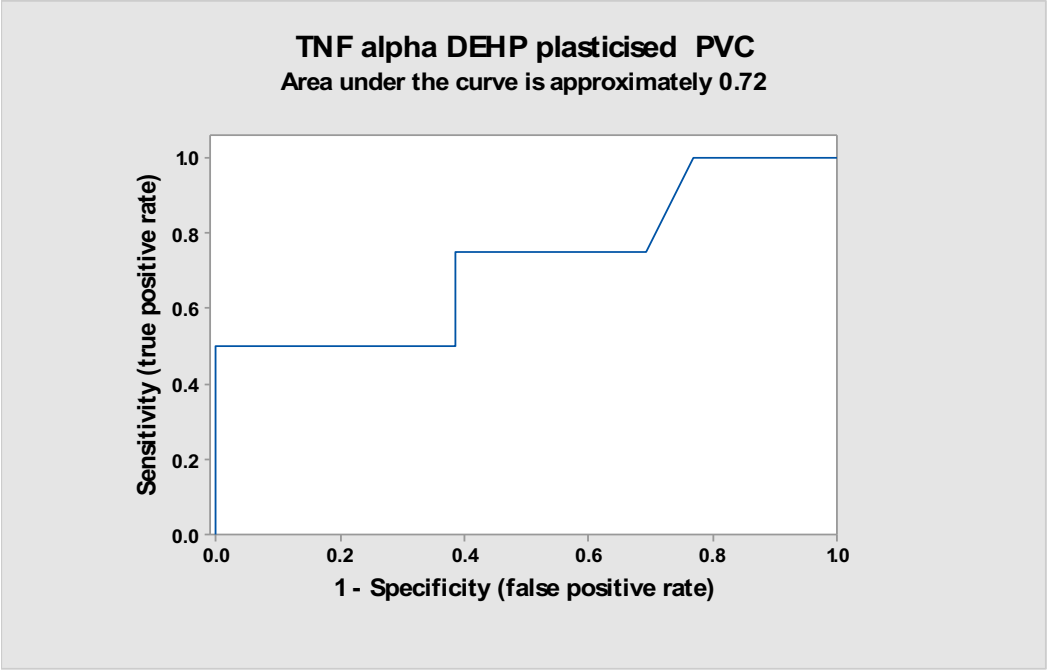

Figure 71: TNF-alpha DEHP plasticised PVC model

Model 4: TNF-α liquid DEHP

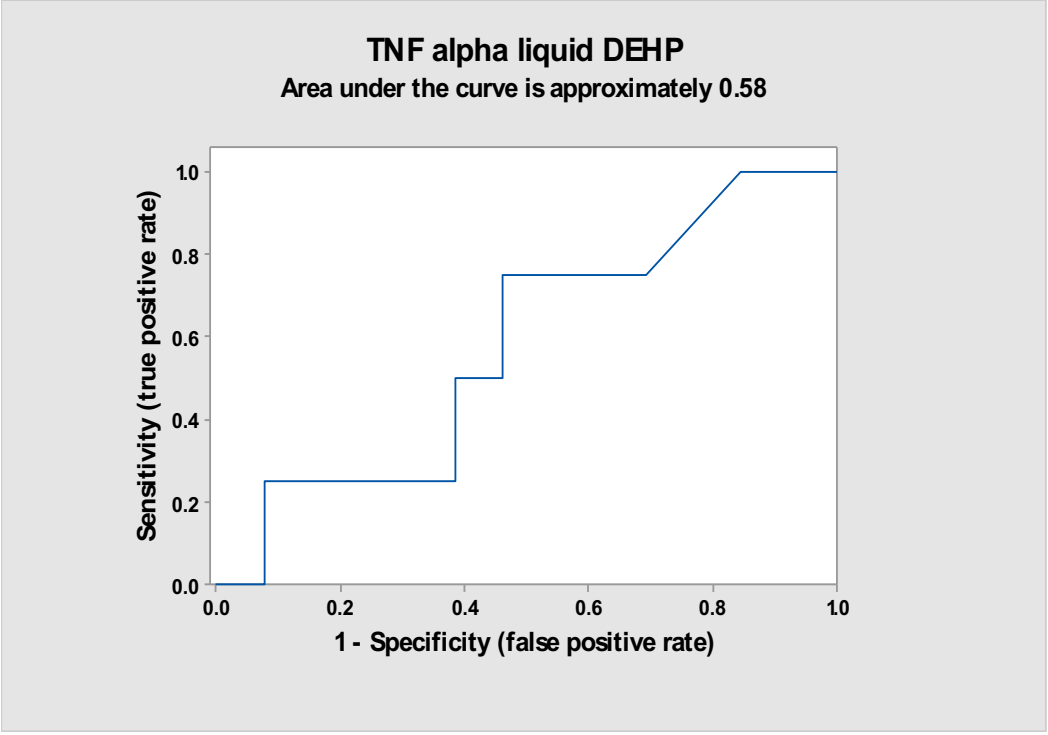

Figure 72: TNF alpha liquid DEHP model

Model 5: CRP DEHP plasticised PVC

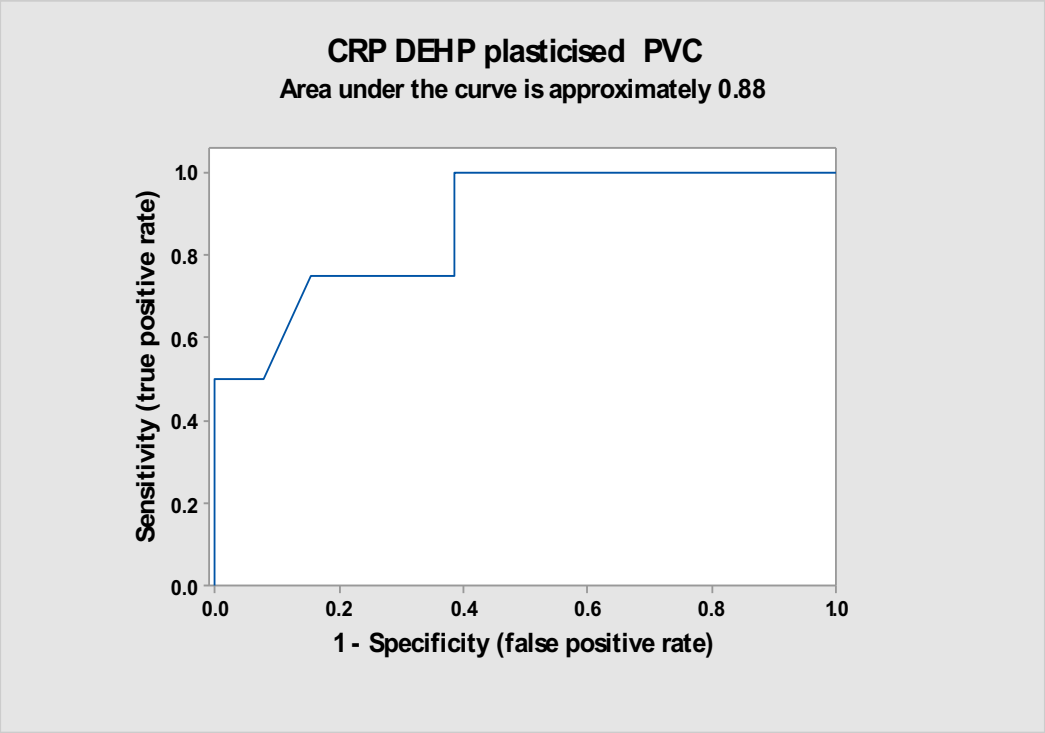

Figure 73: CRP DEHP plasticised PVC model

Model 6: CRP liquid DEHP

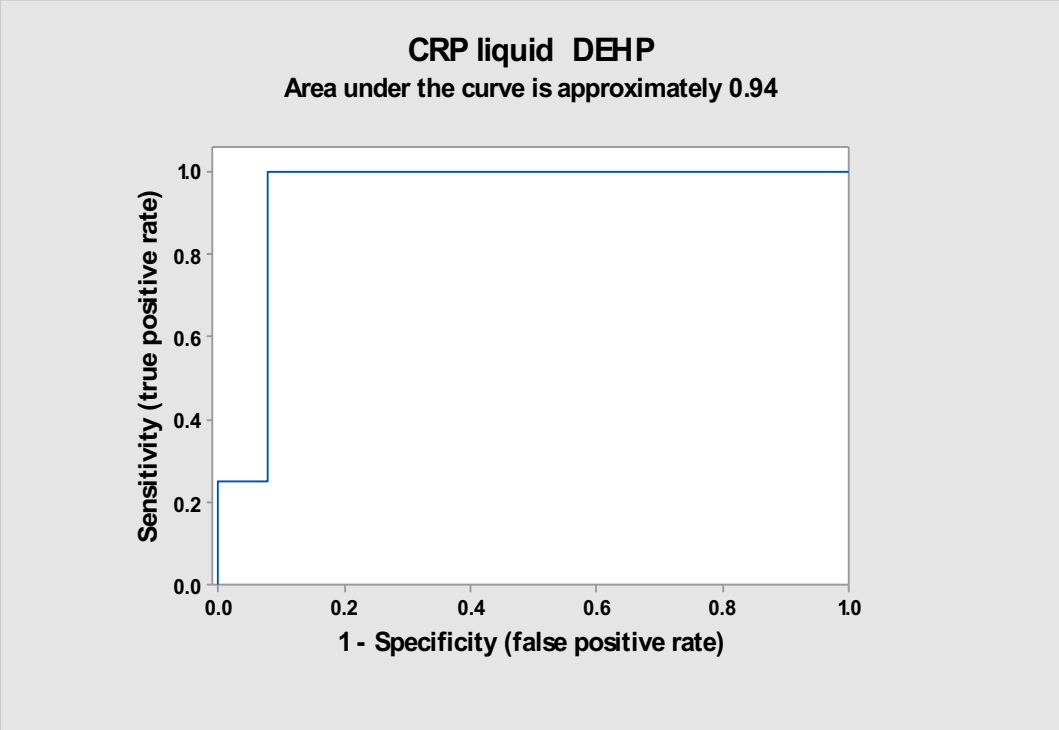

Figure 74:CRP liquid DEHP model

The receiver operating curve, more specifically the AUC, is used to measure the discrimination between different models. Several clinical studies suggested the use of receiver operating curve to evaluate the diagnostic data (Zou, O'Malley, and Mauri 2007). Hence, according to Hosmer definition of the area under the curve, IL-6 DEHP plasticised PVC showed a higher AUC (0.96) as compare to other predictors.

There are many indicators that can be used to test the goodness of each model in addition to AUC such as AIC, predictive power, and odd ratio. All of these results are shown in table 28 below.

	Test		Models					
			IL-6 DEHP Plasticised PVC	**IL-6 Liquid DEHP**	**TNF alpha DEHP plasticised PVC**	**TNF alpha liquid DEHP**	**CRP DEHP Plasticised PVC**	**CRP liquid DEHP**
Goodness of fit	Deviance	P value	0.765	0.584	0.712	0.733	0.677	0.864
	Pearson	P value	0.227	0.463	0.249	0.25	0.79	0.543
	Hosmer-Lemeshow	P value	0.364	0.81	0.3	0.323	0.558	0.812
	Odd ratio		1.0279	1.0257	1.0745	1.0839	1.0424	1.0488
	AIC		**23.88**	**30.11**	**32.06**	**34.06**	**31.61**	**28.29**
	Area under the curve (AUC)		**0.96**	**0.94**	**0.72**	**0.58**	**0.88**	**0.94**
	Predictive power (R^2)		35.44%	28.56%	26.65%	25.43%	27.52%	31.41%

Table 28:Summary findings from the models (IL-6 DEHP plasticised PVC, IL-6 liquid DEHP, TNF-α DEHP plasticised PVC, TNF-α liquid DEHP,CRP DEHP plasticised PVC and CRP liquid DEHP).

All six models showed a good fit of the observed data based on the three different goodness of fit tests (deviance, Pearson and Hosmer-lemeshow). All of them showed higher p values > 0.05 which is a good indicator of the goodness of these models.

Odd Ratio is another statistical tool used to measure the association between the variables and the outcomes or the response. In these models, the variables are IL-6

DEHP plasticised PVC, IL-6 liquid DEHP, TNF-α DEHP plasticised PVC,TNF-α liquid DEHP, CRP DEHP plasticised PVC and CRP liquid DEHP and the outcomes is SIRS. From the table, all models presented a strong association with SIRS (odd ratio above 1).

The predictive power is also considered as another indicator of the goodness of the model. The rule stated that higher is better. Hence, IL-6 DEHP plasticised PVC seems to be the best model based on the R^2 (35.44%). However, further investigation will be performed to choose the best model.

AIC is the best indicator of the best fit model of the data. Smaller AIC indicates the best model. IL-6 with DEHP plasticised PVC is the smallest AIC value (23.88) which means that IL-6 with DEHP plasticised PVC initiator is the sensitive inflammatory marker that can detect SIRS patients prior to OHS.

P cut off values were specified from the receiver operative curves of all models based on the sensitivity and specificity probabilities. Then, use this probability backward on the regression equation in order to calculate the threshold score of the cytokines. Table 29, demonstrated all threshold scores of all models. As the best model is IL-6 DEHP plasticised PVC, the threshold is 200 pg/ml. Any patient who has IL-6 higher than 200 pg/ml may be at risk of SIRS. Hence, all patients' results were tested for false positive and false negative based on the threshold values (table 30). The results were displayed in table 31 and table 32.

Model	Regression equation	P cut off value	Threshold value pg/ml
IL-6 DEHP plasticised PVC	P cut off = -5.34 + 0.0276 IL-6 DEHP plasticised PVC	0.18	200
IL-6 liquid DEHP	P cut off = -4.88 + 0.0254 IL-6 liquid DEHP	0.19	199
TNF-α DEHP plasticised PVC	P cut off = -8.49 + 0.0719 TNF-α DEHP plasticised PVC	0.1	119.5
TNF-α liquid DEHP	P cut off = -8.96 +0.0806 TNF-α liquid DEHP	0.1	112.4
CRP DEHP plasticised PVC	P cut off = -7.66 + 0.0415 CRP DEHP plasticised PVC	0.57	198.3
CRP liquid DEHP	P cut off = -7.59 + 0.0477 CRP liquid DEHP	0.47	169

Table 29:Predictors threshold values based on the sensitivity and specificity analysis.

Having identified the appropriate threshold values for IL-6, TNF-α and CRP for predicting SIRS through the statistical analysis described above, it is possible to revisit the analysis of predictive fit carried out earlier in this chapter using statistically derived threshold values rather than simply observed values. This analysis is shown below in table 30.

Patient number	SIRS (Y/N)	IL-6 DEHP plasticized PVC > 200 pg /ml	IL-6 Liquid DEHP > 199 pg/ml	TNF alpha DEHP plasticised PVC>119. 5 pg/ml	TNF alpha liquid DEHP >112.4 pg/ml	CRP DEHP plasticized PVC >198.3 pg/ml	CRP liquid DEHP > 169 pg/ml

Table 30:Comparison of known IR status in the patient population with the statistical results (regression analysis). The table describes conforming results, false positive results (green) and false negative results (red) for all configurations. The summary of this table is shown in the following table (table 31).

Predictors	Prediction percentage	False positive	False negative
IL-6 DEHP plasticized PVC	66.7%	3	4
IL-6 liquid DEHP	50%	4	6
TNF-α DEHP plasticised PVC	50%	3	6
TNF-α liquid DEHP	41.6%	4	7
CRP DEHP plasticized PVC	41.6%	3	7
CRP liquid DEHP	58%	2	5

Table 31:Analysis of the predictive capability of all configurations of markers and initiators based on the regression analysis models.

The summary outcomes data from statistical analysis confirmed the sensitivity of IL-6 DEHP plasticised PVC in the prediction of SIRS patients. These data were compared with observed ELISA data and the result is shown in table 32.

Predictors	Observed ELISA Correct prediction percentage	Statistical correct prediction percentage
IL-6 DEHP plasticised PVC	66.70%	66.7%
IL-6 liquid DEHP	50%	50%
TNF-α DEHP plasticised PVC	83.30%	50%
TNF-α DEHP liquid DEHP	75%	41.6%
CRP DEHP plasticised PVC	41.60%	41.6%
CRP liquid DEHP	50%	58%

Table 32:Observed ELISA SIRS prediction Vs Statistical analysis prediction.

IL-6 DEHP plasticised PVC is the most sensitive predictive marker due to its high prediction percentage of SIRS outcome patients (66.7% statistically and 66.7% from the the observed ELISA). Also, it has lowest number of false positive and false negative values, smaller AIC (23.88) and higher AUC (0.96) when compare to other predictors.

7.5.4 Patient age and Systemic inflammatory response syndrome (SIRS)

Presently we have investigated pre-surgical cytokines as predictive indicators of the complexity of post-operative recovery, in particular of SIRS related complications. It is however, important to consider whether there are any other indicators, perhaps less complex in terms of measurement, that might also give good indication of post-op status. Our analysis has already eliminated EuroScore as a potential screening test, but there is anecdotal evidence that age may be to some degree a marker of post-operative complexity. We therefore carried out a regression analysis with age as the determining factor. In this model, the predictor is the age and the response is SIRS.

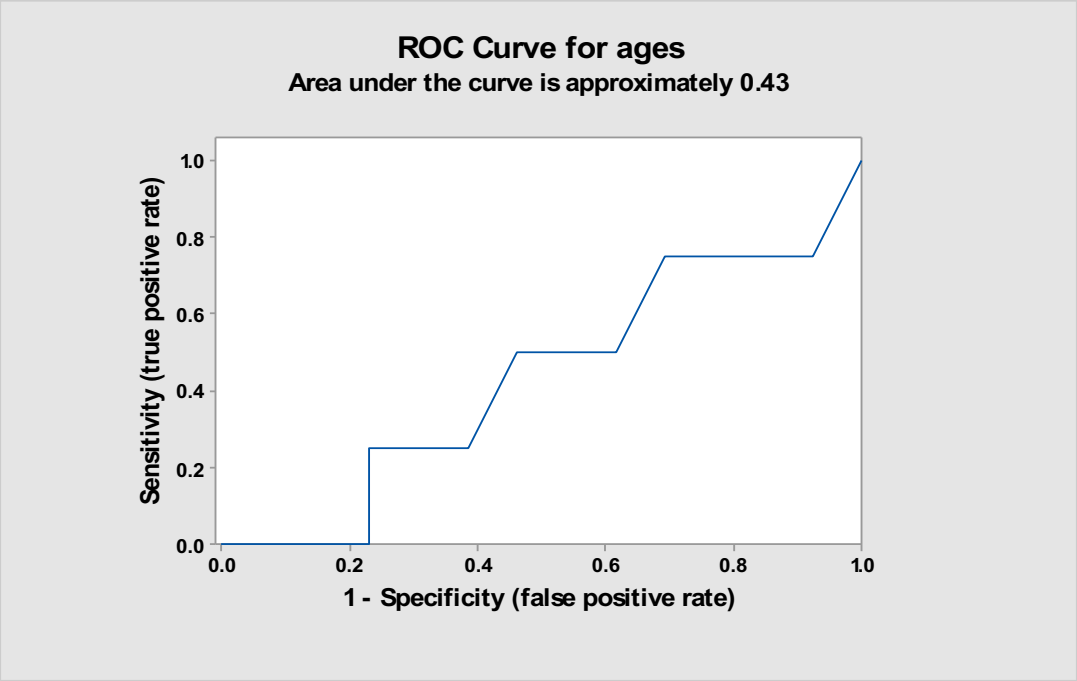

Figure 75:Patients' ages receiver operating curve.

The results showed there is no significant relation between the ages and the occurrence of SIRS by three different methods. Firstly, odd ratio is less than 1 (0.9747) which means that there is not association between ages and and systemic inflammatory response syndrome. Secondly, the predictive power is 1.43 % which is

relatively small. The predictive power indicates that this model is not a good to fit the data. Finally, the area under the curve (AUC) is 0.43 which means the curve is not adequate to fit the data.

7.6 Fourier transform infrared spectroscopy (FTIR) Results

As outlined in the previous chapter, two methods for measuring cytokine levels were to be considered in the context of this program of work, a conventional ELISA approach and the application of Fourier transform infrared spectroscopy (FTIR). The objective of this process was to ascertain the most appropriate method of measurement for our proposed screening test system. To answer this question, we carried out measurements using both systems on the same population of blood samples harvested from our patient group. The critical factors to be considered in this section of the work were accuracy (taking the ELISA data as the gold standard), processing volume and processing time.

All spectrometer scans represented patients' plasma absorbance at different wavenumbers. There were two spots for each patient sample. The total number of samples analysed therefore was 416 (static control, dynamic control, DEHP plasticised PVC and liquid DEHP). As seen in figure 76, the absorbance of each sample was taken by calculating the mean of two dry scans of the two spots and then plotting the range of absorbances against the wavenumbers. DEHP plasticised PVC and liquid DEHP results were higher in the majority of those patients when compared to the corresponding control samples. This is confirming the activation effect already identified with the ELISA approach. For analysis purposes the peak absorbance of each spectrum was considered to represent the peak concentration level of each sample. Control samples of known concentration were process to

produce a standard concentration curve for the assay, and this process is shown in figure 77.

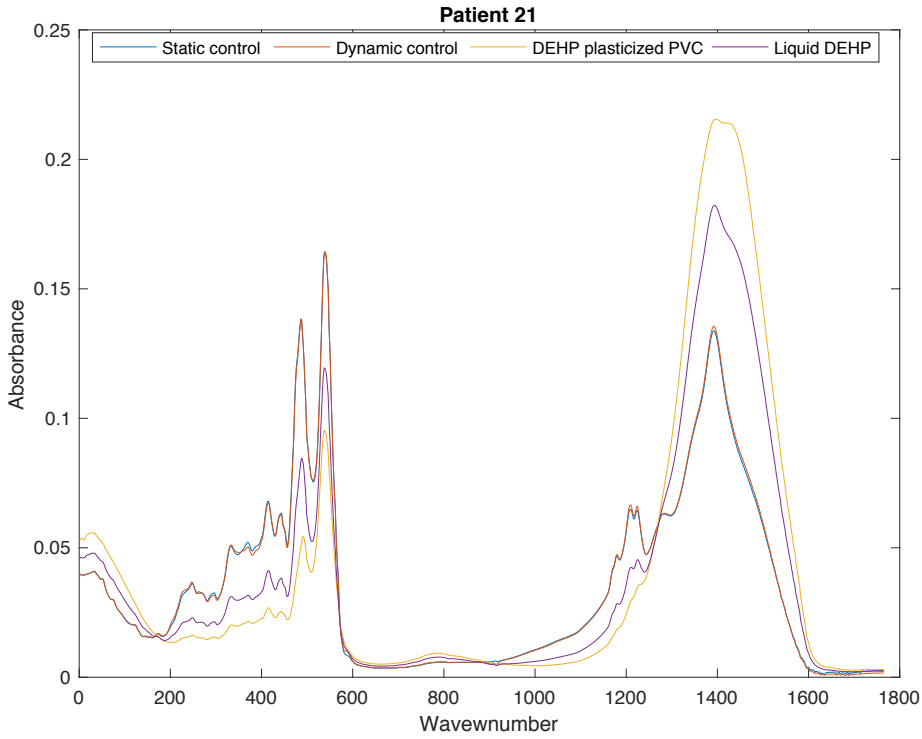

Figure 76:Representative FTIR spectrum results.

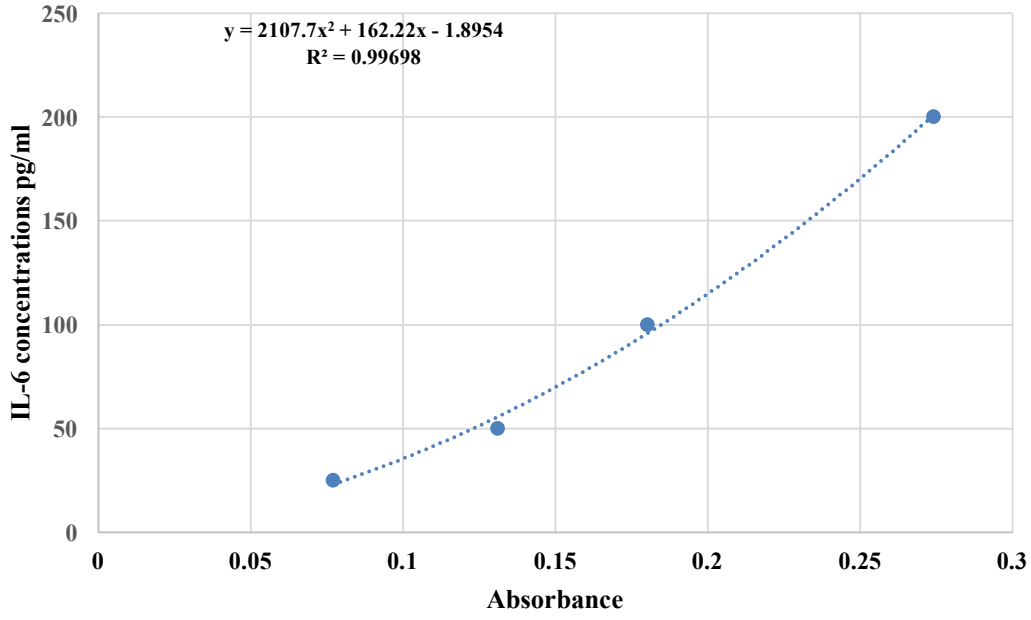

Figure 77:FTIR standard control curve.

The scanning process was then carried out on all blood samples and the corresponding cytokine concentration calculated using the standard curve trend equation. The result of this process can be seen in table 33 where comparative data can be seen with the ELISA derived sample data. This process was carried out on samples involving DEHP plasticised PVC initiator and IL-6 as the marker as this had already been shown to be the most appropriate marker for the screening process in terms of patient outcome measures.

The raw scan data for each sample can be seen in Appendix I.

Table 33:ELISA and FTIR data for IL-6 DEHP plasticised PVC.

Comparative derived data form the FTIR and ELISA processes are shown below in figure 78. There were differences in the absolute values derived from these two processes, but further analysis of overexpressing samples (200 pg/ml and above) were further analysed and similar trends were identified between the two methods, Table 34. The patients extracted from this sifting process, (Patient 3, patient 7, patient 23, patient 24, patient 25, patient 26, patient 27, patient 28, patient 33 and patient 34 and patient 40) all showed over expression of IL-6 in response to the DEHP plasticised PVC stimulus. These patients were further analysed in relation to their post-operative SIRS status (Table 34) where the relationship between measured values above 200pg/ml and SIRS status was seen to be closely related. Of the 11 patients identified by this threshold method, 8 (72.7%) were identified by both methodologies and 3 (27.3%) were seen to be false positive values. There were no false negatives in this group. These data suggest that this method, applied to both the ELISA and the FTIR techniques returned the most sensitive screening of patients with a propensity for post-operative SIRS and furthermore, that there was equal sensitivity using both analytical techniques. The results suggest that both the ELISA and FTIR techniques are both suited to the further development of a POC SIRS screening device. However, the FTIR approach was less complex, faster and more suited to the development of a sensor technology for this screening process. The ELISA technique, albeit the gold standard for the measurement of biological markers, is time consuming and requires multiple processing steps, and would therefore require the development of a more complex and less user friendly technology.

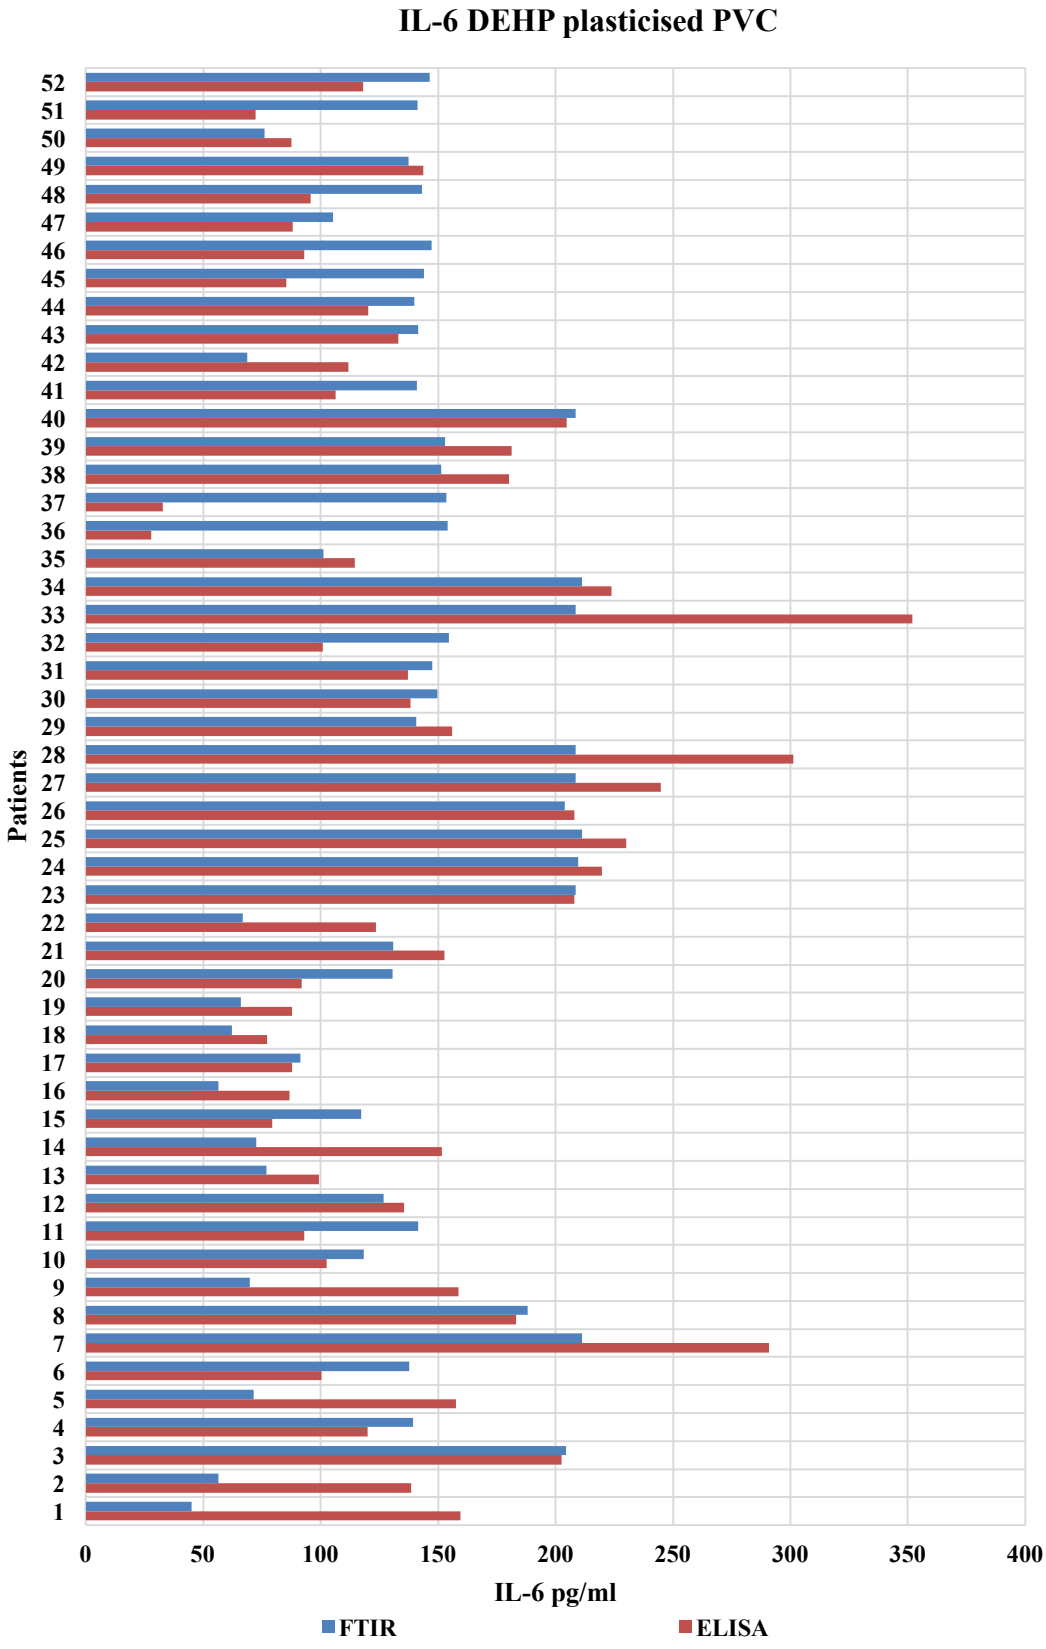

Figure 78:Patients' IL-6 DEHP plasticised PVC scores with ELISA and FTIR.

Patient number	ELISA	FITR absorbance	FITR concentrations pg/ml	Post-operative complications

Table 34:Patients who develop SIRS with both ELISA and FTIR techniques.

7.7 Summary

This study has confirmed the following;

1. That DEHP plasticised PVC is a good initiator of inflammatory processes in patient blood.
2. Activated IL-6 in discreet patient blood samples is the best marker of the cytokines tested of the propensity for heightened IR to the surgical procedure.
3. The activation of IR, using DEHP plasticised PVC as an initiator and IL-6 as a marker in blood samples taken from patients prior to surgery results in a good correlation with the clinical outcome of patients undergoing open-heart surgery and can be employed as a screening test for the propensity for post-operative SIRS.
4. Other commonly employed indicators of SIRS risk, Age and EuroScore are not sensitive markers for post-operative complications associated with SIRS.
5. The use of a threshold response approach (200 pg/ml and above) to analysing IR activation in pre-surgical samples results in a good correlation with clinical outcome.

6. Both the FTIR and ELISA methods are suited to the development of a screening technology for the propensity of patients to develop SIRS during the pre-surgical phase.
7. The FTIR technique, with its reduced complexity and processing time, is best suited to the development of the intended device.

Chapter 8: Device development

8 : Device development

8.1 Device development

The overriding objective of this thesis is the development of a point of care sensor technology for the assessment of the propensity for patients undergoing open heart surgery to develop a heightened blood/material contact mediated inflammatory response. The significance of the IR to OHS has already been described in previous chapters, but this is one of the most challenging complications of OHS and to date is largely treated in a responsive manner in the ITU setting. The purpose of this screening process is to identify those patients who are at risk from this response prior to the surgical intervention and to stream these patients either to a different treatment modality, for example off pump surgery, of to target these patients with the broad array of techniques and technologies designed to moderate its impact, for example surface treatment, haemodialysis, and pharma solutions. These moderating approaches are not generally employed in the general patient population due the cost of doing so. A pro-active response supported by the deployment of the proposed screening sensor would permit the deployment of these technologies in a target patient population, resulting in a reduced additional clinical cost. As described in the previous chapters, there is a process of screening that appears to be reliable in identifying these at-risk patients in the pre-surgical phase that correlates well with the post-surgical outcome. This approach, using materials commonly deployed in the CPB circuitry, DEHP plasticised PVC as an initiator and IL-6 as the marker, can be measured using one of two techniques, conventional ELISA measurement and FTIR. Both appear to be capable of discriminating between the heightened IR patients and the non IR patient populations with a good degree of reliability. In terms of

developing the sensor technology itself, these techniques require a different approach to sample processing. The ELISA technique would require a complex sample pathway involving the use of a lateral flow strip system (Figure 79) that will perform sample activation, sample separation (plasma extraction), followed by the ELISA process itself and terminating with a concentration measurement step using a reader. The FTIR system is a much simpler system that requires no sample preparation insofar as it measures concentration unprocessed plasma samples, but still requires a blood activation step and sample concentration measurement step (Figure 80).

One additional key difference between the two systems is the processing time between the two systems, ELISA taking in the order of 60 minutes whereas with the FTIR samples can be processed in less that 10 minutes. This suggests that for a rapid screening test, the FTIR would be the most suited approach.

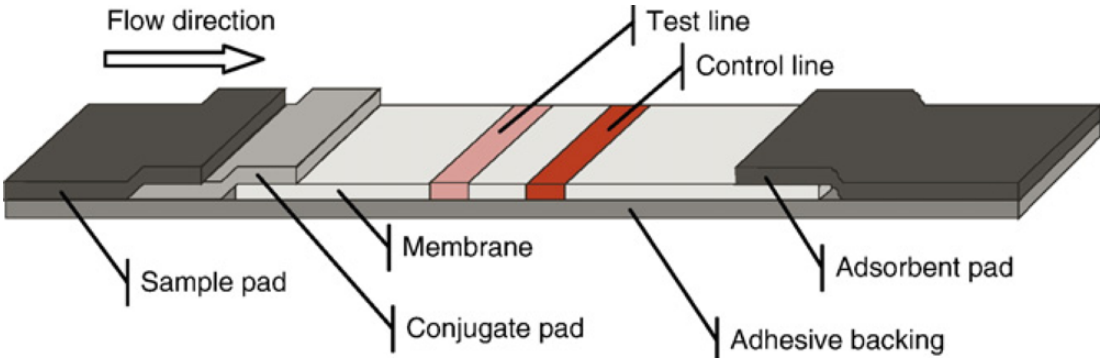

Figure 79:Lateral flow strip (LFS) components(Assadollahi et al. 2009).

Figure 80:Gemini Analyser by Thermo Fisher. This a hand held FTIR/Raman analyser that is capable of measuring single samples in a similar manner to that of the laboratory device employed in the body of this work**. (Taken from : https://store.federalresources.com)**

Key to the development of the technology proposed in this work that the device developed should be portable and capable of measuring the molecular target with some accuracy and critically to identify those samples that are overexpressed beyond a particular threshold value, as described in the previous chapter. Both the ELISA and handheld FTIR approaches are capable of meeting these requirements, however, the FTIR approach will do this with fewer processing steps.

The two systems have one common requirement, that the blood sample taken from the patient can be activated and the plasma separated. The overall sample processing scheme is shown in figure 81.

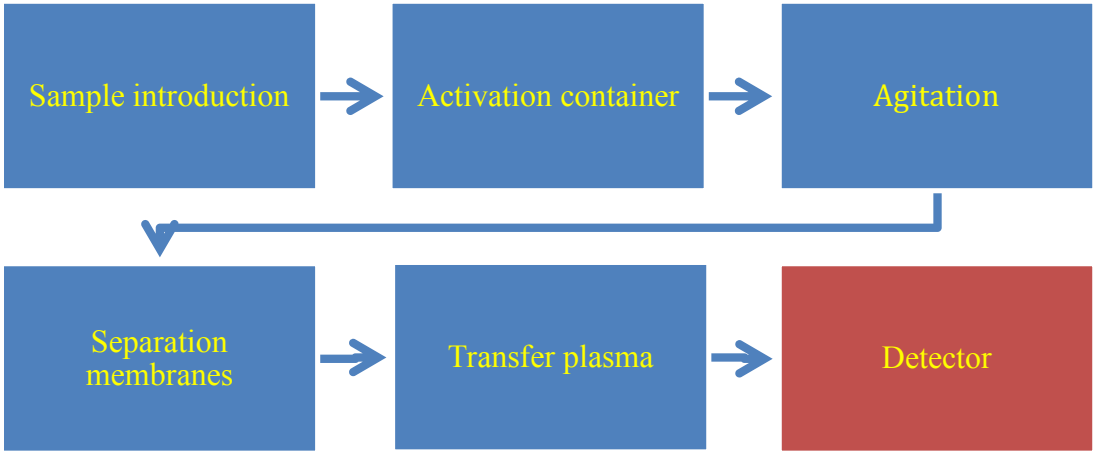

Figure 81:Schematic diagram of the measurement procedure.

Common to both approaches is the need to agitate the blood samples prior to plasma separation and sample measurement. To achieve this, irrespective of the measurement approach, a technology would need to be developed that achieves the sample preparation objective. To this end an activation chamber was developed that was designed to mix the sample when in contact with the activating material.

8.1.1 Activation chamber

The activation chamber has two functions, firstly, to act as a blood reservoir in which the blood can exposed to the activating agent and secondly as a vessel in which the blood /activating mixture can be agitated to evaluate exposure.

The basic design was to create a blood mixing chamber with a breakaway section to extract the blood after processing, with the agitation being provided by a DC motor attached to the lower aspect of the chamber. A design was developed for this element of the technology, with the overall dimensions of the chamber being defined by the

size of the DC motor employed. The design was carried out using Creo software, figure 82. The use of the Creo sofware permitted direct 3D printing of the component for rapid laboratory experimentation. As can be seen from the rendering in figure 82, the design incorporates a container for blood processing and a "snap-off" section for plasma extraction, provided by the thinner walled frontal section of the chamber. The snap-off function was further enhanced by the inclusion of a grooved inclusion on both lateral aspects of the thin walled element.

This component was configured to be compatible with the 3D printing techniques described below.

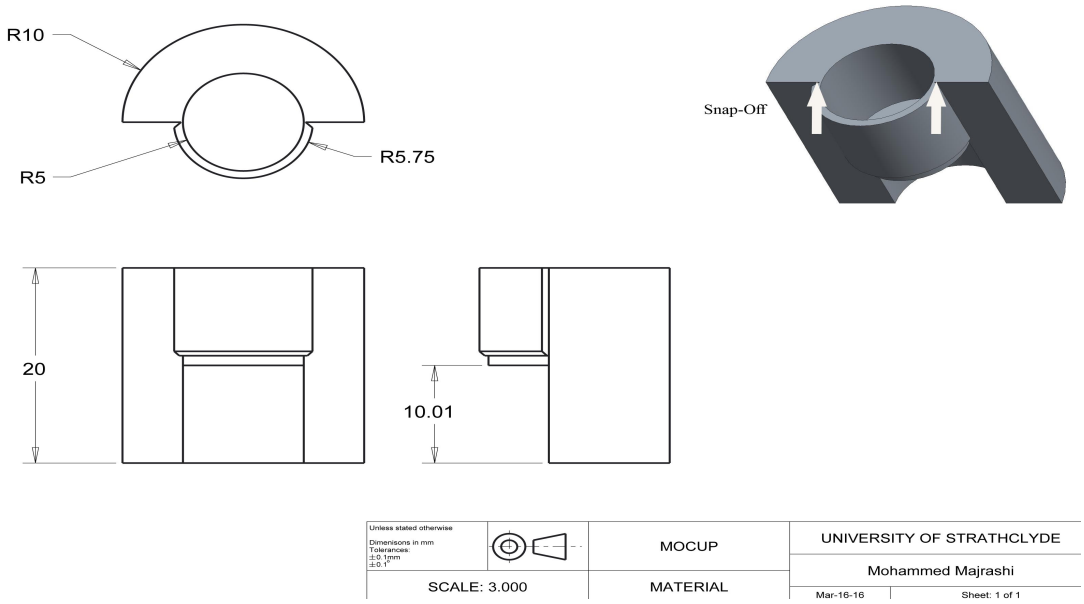

Figure 82:3D design of the activation chamber. The design has the following dimensions: height 20 mm, radius of the upper side is 10 mm, radius of the thin layer (which will be used to attach with the seperation membrane to allow plasma absorption process) is 5 mm.

3D printing

Three dimensional printing is a manufacturing technology aimed to produce an object from different ranges of materials such as ceramics, plastic, metal, liquid and living cells via a fusion and deposition process.

In recent years, there is an increase demand on 3D prinitng applications specifically in healthcare (Schubert, van Langeveld, and Donoso 2013). Crucially, from the medcial device perspective, 3D printing offers a degree of versatility in design and manufacture the allows the generation of highly complex and application specific components (Banks 2012). Presently, 3D applications are impacting on many areas of manufacturing practice, including the medical and health sector. This technique has significantly accelerated the product development cycle and has led to a shorteneed concept to development to delivery time.

Medical application of 3D printing are classified into several categories such anatomical models,organ fabrication, custom prostheitcs and implants.(Klein, Lu, and Wang 2013).

In the present work, 3D design of the device, in this case the exposure container was printed according to the steps in table 35.

Steps	Descritopn
1	Design the object by using a creo software and save the object as STL file.
2	Upload the file and open it with a simplify 3D (version 3.1.1) software.
3	Manipulate the design to be suited for printing.
4	Send the command to the printer and wait for the final product.

Table 35:Activating chamber printing steps.

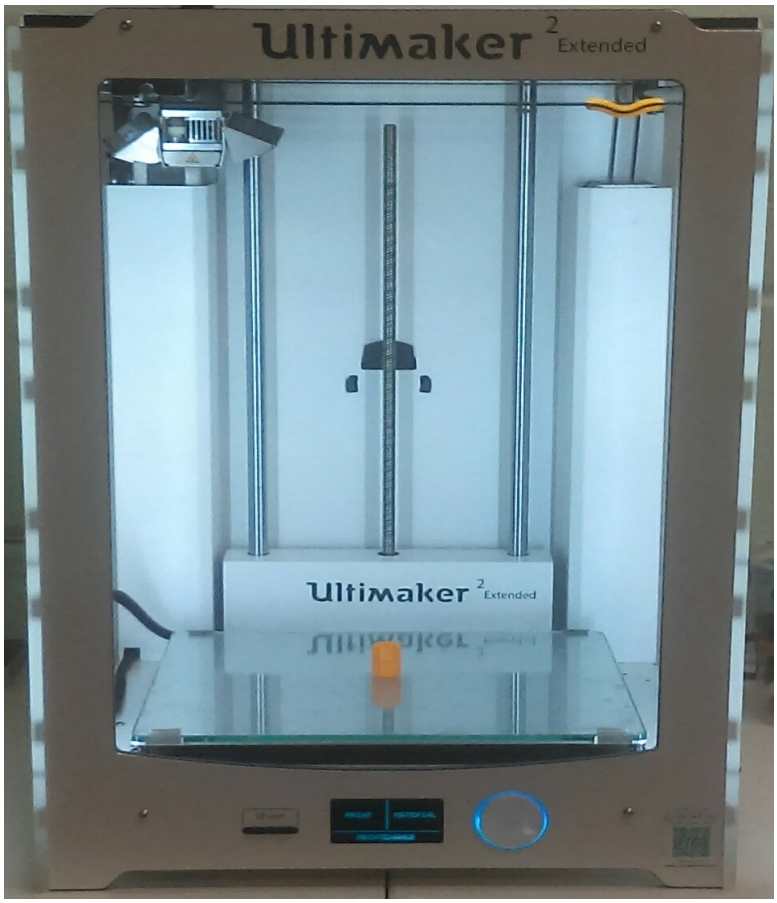

Figure 83:Ultimaker 2 extended 3D printer. It was used to print the exposure container chamber that will explained in the following section.This printer used PAL (Polylactic acid) material in the printing process of the object.

Once printed, the DC motor was connected to the underside of the chamber and the fundction of the device tested. The DC motor was utilised to provide the agitation function through the generation of vibration to the chamber. The DC motor utilised (Pinzhi Co. Ltd, Fujian,China) is typically emlpoyed to provide the vibration alert in mobile telephone equipment and were through suited to the proposed purpose. To test the function of the assembled devices, as series of experiments were carried out. These are detailed in the following section of this thesis.

8.1.2 Testing the Function of the Activation Chamber

These experiments were designed to validate the efficacy of the proposed design of the activation chamber. In these experiments, bovine blood was introduced into the chamber which had been primed with ground DEHP plasticised PVC as the initiator material. The overall protocol is described in table 36. Bovine blood came in contact with grounded DEHP plasticised PVC initiator according to the described protocol in table 36, and a representation of the experimental setup is shown in figure 84.

Steps	Description
1	1 ml bovine blood plus 0.2 gram DEHP plasticised PVC were loaded onto the activation chamber. Another 1 ml blood was used as static control (without DEHP plasticised PVC).
2	DC vibrating motor was placed on the bottom side of the activation chamber (exposure container), and connected to the power supply.
3	Agitate blood with DEHP plasticised PVC starting by 1.5 V for three different time periods (10 min, 30 min and 60 min).
4	Remove blood and spin by centrifuge to get the plasma
5	Freeze all samples at -80°C for further analysis
6	Repeat the same steps with 3Volt.

Table 36:Bovine blood protocol(activation chamber)

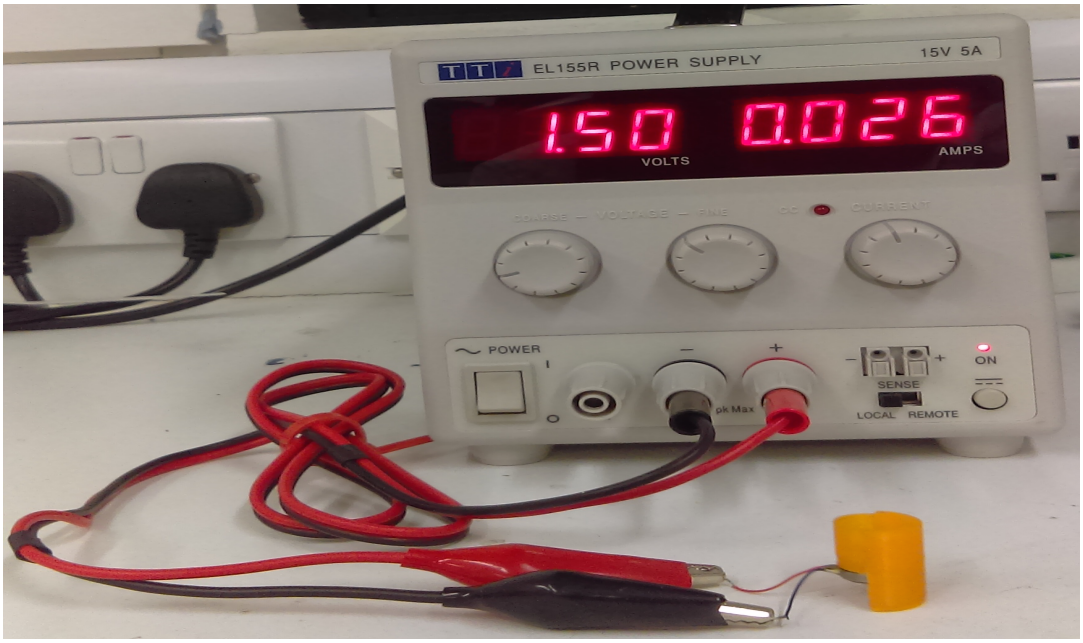

Figure 84:Experimental set up(DC motor, exposure container and power supply generator). 3V DC motor (10mm x 2.7mm) was used to generate motional vibration agitation of the blood with the ground DEHP plasticised PVC. This motor generates 1.5 Volt – 3 Volt and the maximum rotor speed is 4000 rpm.

At the end of the agitation process, the blood was removed from the chamber and was processed for IL-6 measurement using the ELISA technique.

IL-6 measurements

The objective of this section of the work is to determine that it is possible to achieve IL-6 upregulation through the deployment of the new activation chamber and associated technology over a given time period of exposure (10 min, 30 min and 60 min) and at 2 different agitation rates (shown as 1.5 and 3 volts supply to the motor assembly) using bovine blood freshly harvested from the local abattoir (Sandyford farm, Paisley, UK). Comparison will be made with control samples in which no initiator agent is employed to ascertain that contact activation is being achieved and to determine the activating effect of the chamber itself.

In keeping with normal practice, IL-6 standard curves were generated based on the manufacturer's protocol (RD systems a biotechne brand, Abingdon Science Park UK). Trendline equations were applied to calculate IL-6 concentrations of each sample (Figure 85).

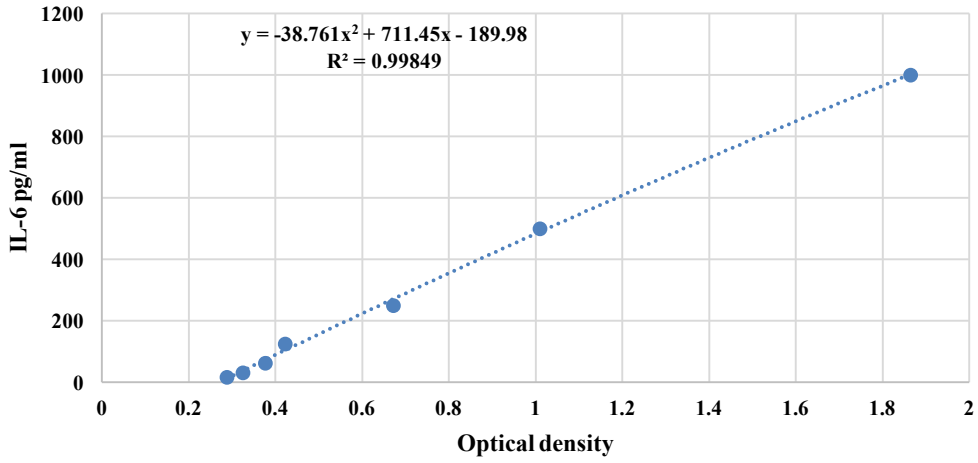

Figure 85:Representative IL-6 standard calibration curve. All IL-6 standard curves can be seen in Appendix J.

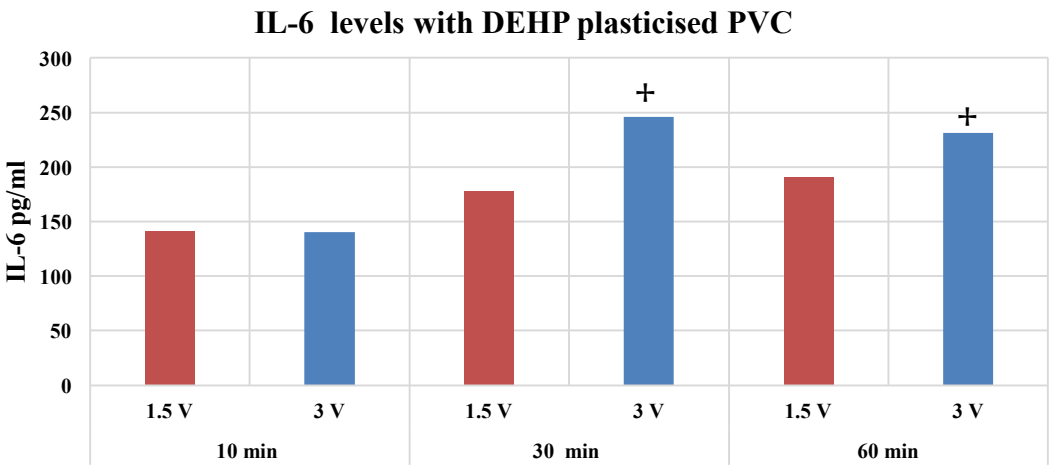

Figure 86:IL-6 concentrations in pg/ml with 1.5 Volt and 3 Volt at different agitation times (10 min,30 min and 60 min) (n=3).

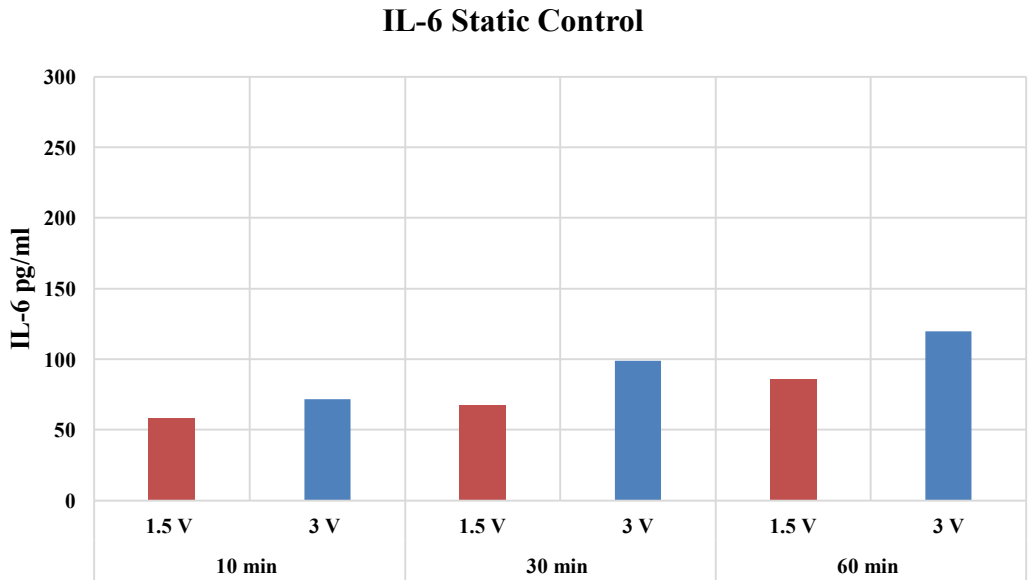

Figure 87:IL-6 static control concentrations at different agitation times. These data represented IL-6 levels of the static control blood which kept away from the agitation process (n=3).

The results showed a statistically significant difference between IL-6 levels with 3V and 1.5 V after 30 and 60 min respectively (p=0.038, p=0.04). these outcomes suggested that the most appropriate agitation speed can be achieved after 30 min (4000 rpm). The data also demonstrated that there was a statistically significant

difference between the static and dynamic samples in terms of the level of activation observed (119.75 pg/ml vs 231.28 pg/ml p=0.011 after 10,30 and 60 minutes). This confirms the activation effect of the initiator agent (DEHP plasticised PVC) and that the system itself is not a significant initiator of IL-6. Critically, one might anticipate that "heightened expressers" of IL-6, those at risk patients, will show a heightened response to the screening system, but this remains to be demonstrated in clinical practice.

8.1.3 Separation membrane

Having detrmined the configuration of the activation aspect of the system and having demonstrated its efficacy, the next step in designing this device is to assemble a separtation technology that will effectively remove the cellular components of the blood and deliver the plasma component to the reader (FTIR). There are several possible solutions to this, mechanical and membrane based that could effectively achive this key element of the sample processing procedure. Mechnical means, might involve the use of micro-centrifuge or magnetic flea technology to separate the cellular components, followed by a micro-pumping approach. Such an approach would be both complex and costly and may be challenging in terms of the re-usability of the system. The alternative approach is to utilise specific membrane technogies to firstly separate the blood cell form the liquid (plasma) component, followed by transporting the plasma by a wicking process to the reader assembly. This technique is commonly used in the lateral flow strip technology utilised for some molecular measurements. Such a process may consist of:

(a) Nvivd, a membrane designed by the Pall Corporation, which is used to separate whole blood and plasma. This is a single step process that separates

the plasma from the whole blood, and is sold as an alternative to microcentrifuge devices. These membranes come in various configurations for a number of different applications (Table 37). The membranes for different target applications have somewhat diffent characteristics and structures which we have observed using an SEM (see following section). Critcally, all of these membrane types are capable of separating a volume of blood (depending on the application) in less that 2 minutes, a factor that is central to the development of a rapid screening assay.

(b) A wicking membrane to transport the plasma to the reader assembly, see section 8.1.4

Membrane	Membrane grade	Plasma separation time	Plasma recovery	Comments
Asymmetric polysulfone	GF	<2 min	>=60 %	Small blood volume application, finger sticks
	GX	<2 min	>=60%	
	GR	<2 min	>=80%	Larger blood volume applications such as lateral flow immunochromatographic devices.

Table 37:Plasma separation membranes specifications

(Taken from: http://www.pall.com/main/home.page).

Investigation of the characteristics of Nvivd membranes using a Scanning electron microscope (SEM)

Scanning electron microscope (SEM) is a method for high resolution images of the materials surfaces. The technique based on focusing high energy electron beams in order to capture images at different magnification and different depth of field. The technique is widely used in the biomaterials and materials science fields and permits

close scrutiny of surfaces and surface structures and inclusions. In particular, this approach is suited to the investigation of surface pore structures in membrane surfaces. The devices have advanced considerably in recent times and new desktop devices, such as the one utilized in this study (figure 88) are now replacing older larger and more complex systems.

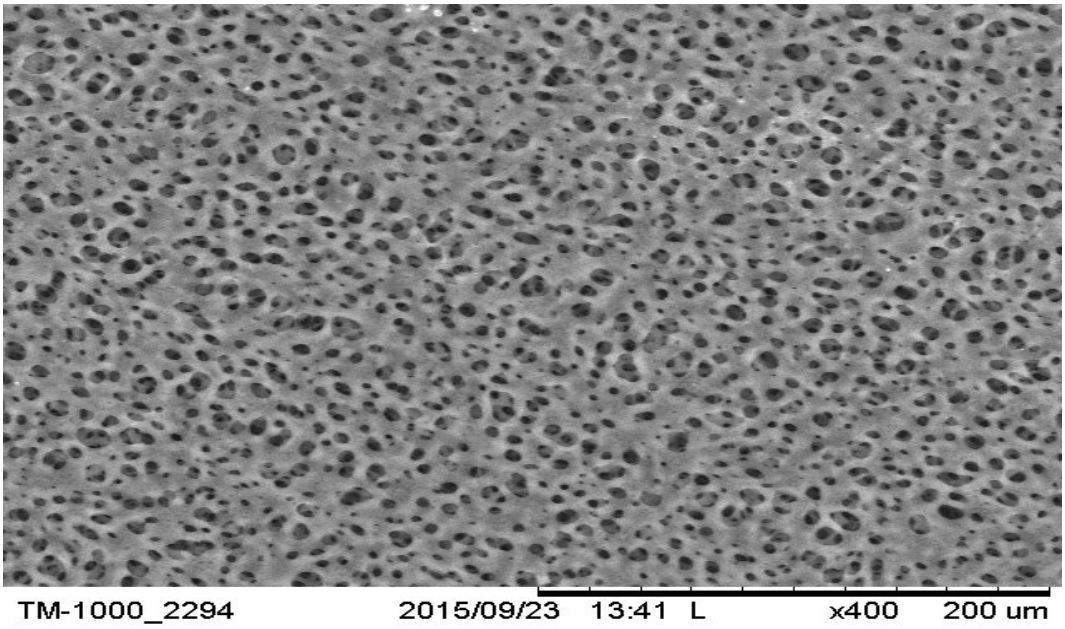
Figure 88:Electron microscope scanning system (Hitachi, TM-1000).

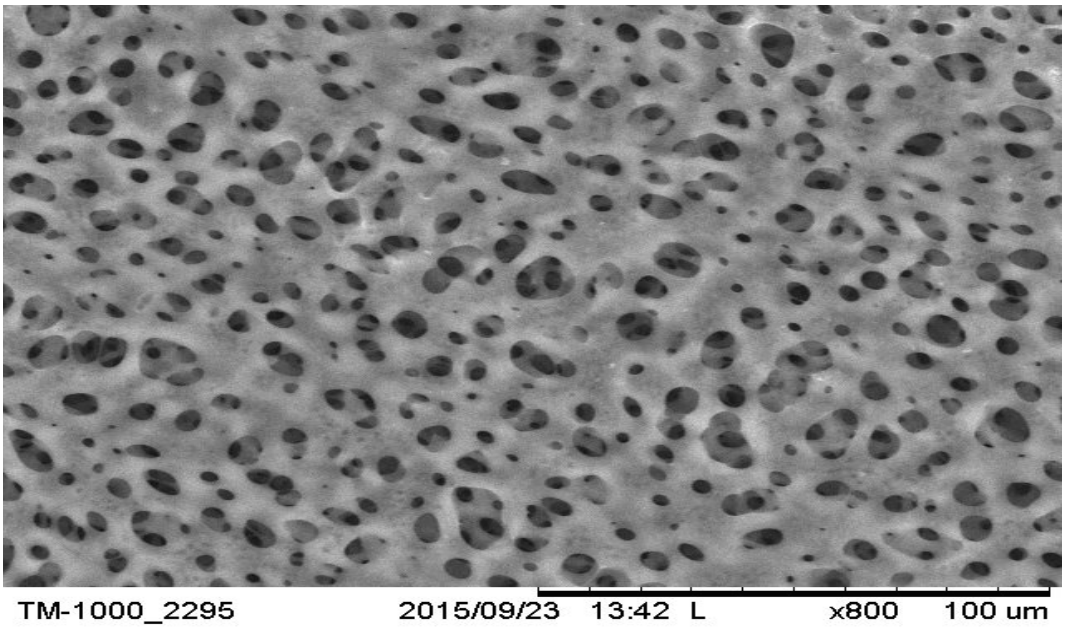
Samples preparation

A small piece of the target material is attached to the specimen stage and then inserted into the SEM chamber. Unlike historical systems, it is not necessary to sputter coat the sample with gold, providing the sample is in a dry state. This makes the scanning process much simpler and less time consuming. The scan can then be carried out at a range of magnifications to determine the high and low level structure of the target material.

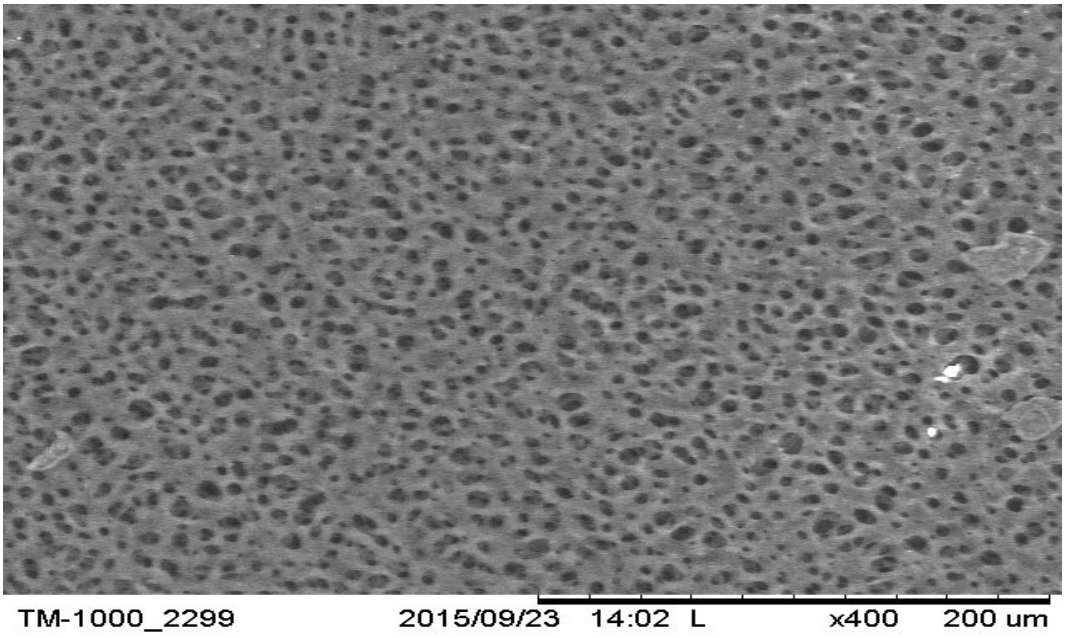
Results

GF membrane





GX membrane



TM-1000_2299 2015/09/23 14:02 L x400 200 um

GR membrane

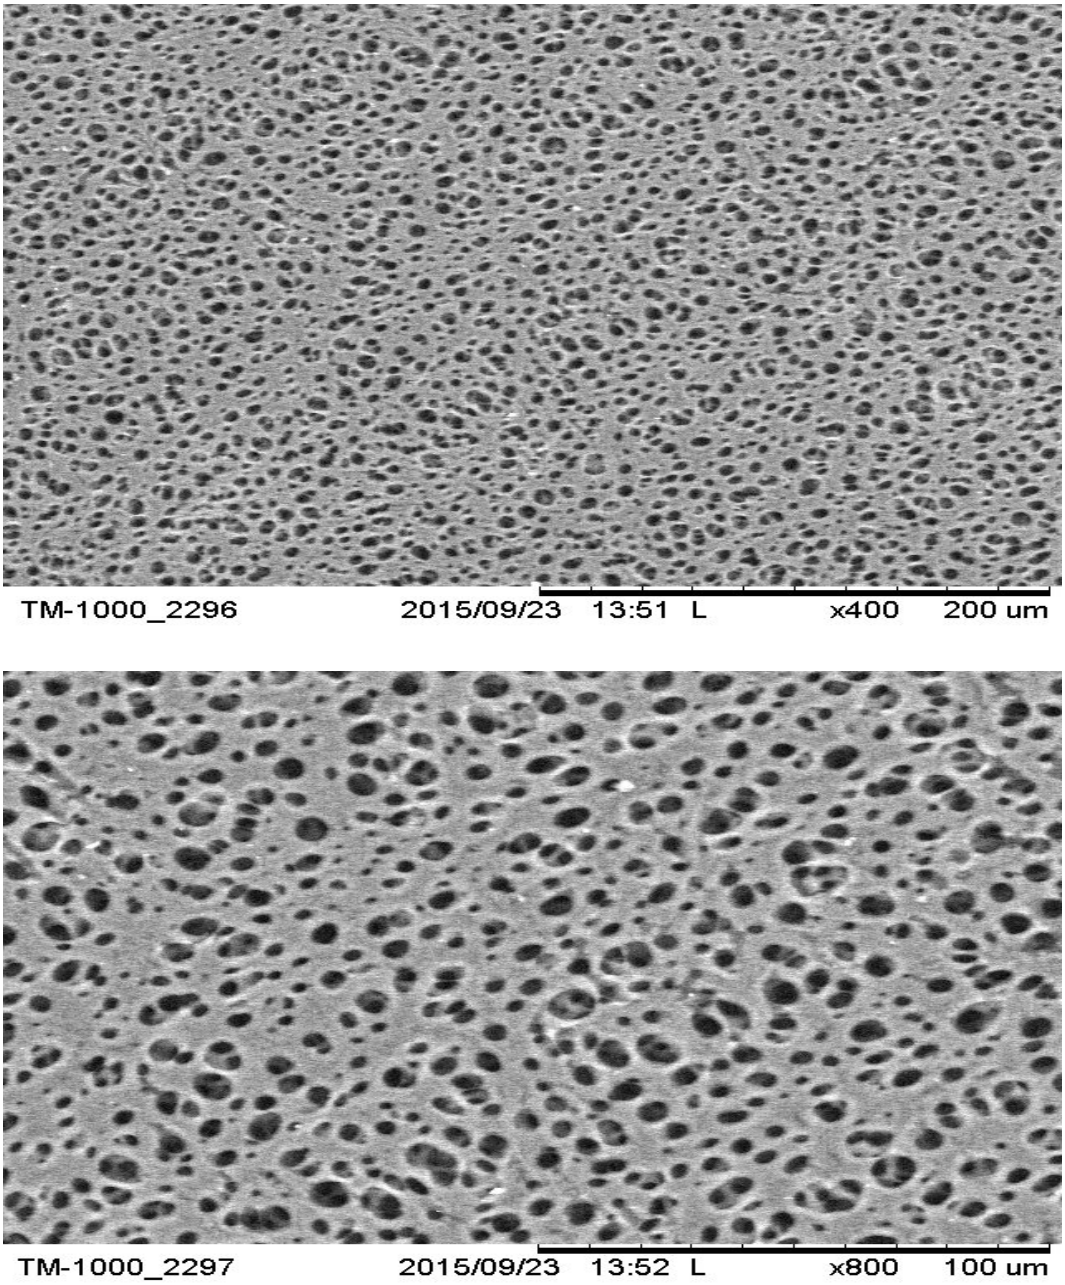

Figure 89:Different scans of the three different grades of separation membranes (plasma separation).

The scanning electron microscope showed a good discrimination between three different types of Pall separation membranes. The surface of the grade GR showed a more porous structure when compared to other grades of membrane (GX and GF)

suggesting that this is the most appropriate membrane configuration for the intended application.

8.1.4 Wicking membrane

The final stage in the sample processing is to carry the plasma separated by the previous step to the measurement device. To achieve this, we propose to employ a wicking membrane assembly, connected to the activation chamber and cell separation membrane assembly. A number of wicking membranes are commercially available and the properties of the most promising of these (from GE Life Science, Berlin, Germany) are outlined below in table 38.

Product	Material	Properties	Thickness (µm)	Wicking rate(s/4 cm)	Water absorption (mg/cm^2)
CF3	Cotton linter	Medium weight	322	174.3	34.6
CF4			482	67.3	49.9
CF5			954	63.3	99.2
CF7		Thick material suitable for high sample volume	1873	35	252.3

Table 38:Wicking membrane specifications.

For a rapid analysis system, the fundamental requirement is that the plasma is "wicked" from the separation step in the process through to the detector as quickly as possible. For this reason, we intend to employ the CF3 membrane, the properties of which are shown above. This membrane has a rapid transfer capability, is relatively thin in profile, therefore suitable to low volume applications, and has a low water adsorption property.

8.1.5 Proposed Device Configuration

This work has outlined the design requirements for a rapid screening sensor technology for the screening of patient propensity for heightened IR to open heart surgery, but may also have applications in other areas of medical/surgical practice. The technology described has a number of steps from sample harvesting through to measurement. These steps require a number of technologies to activate the blood sample, separate the plasma from the whole blood and to carry to plasma through to the measurement device. These technologies that comprise the technology train for this device are outlined below.

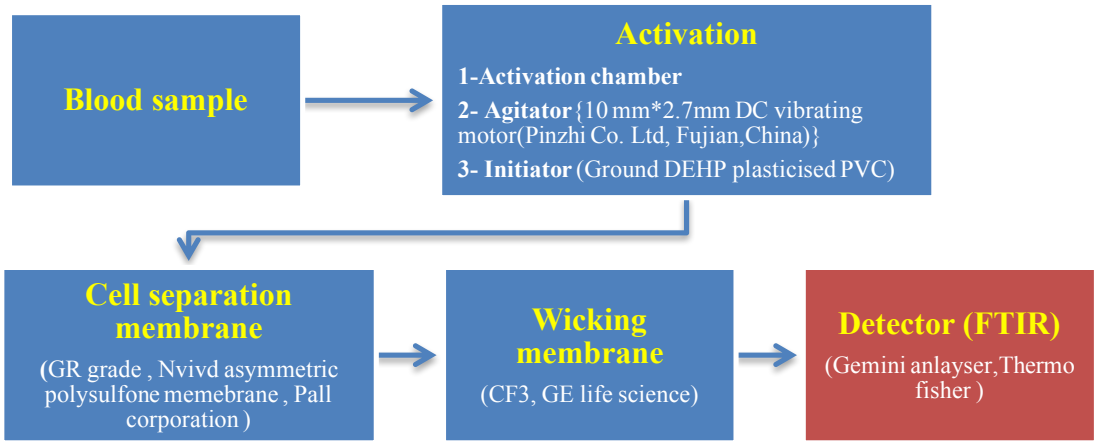

Figure 90:Schematic diagram of the proposed screening test configuration steps.

The technology train is now well defined and each element of this has been tested for conformity with our overall objectives. It is clear that this technology is achievable and that the activation stage (Chapter 8) and the detector elements are viable (Chapter 7). The required plasma separation and transportation vehicles, in the form of two commercially available membranes are available and appropriate for this application, leading to a device design that is shown below (Figure 91).

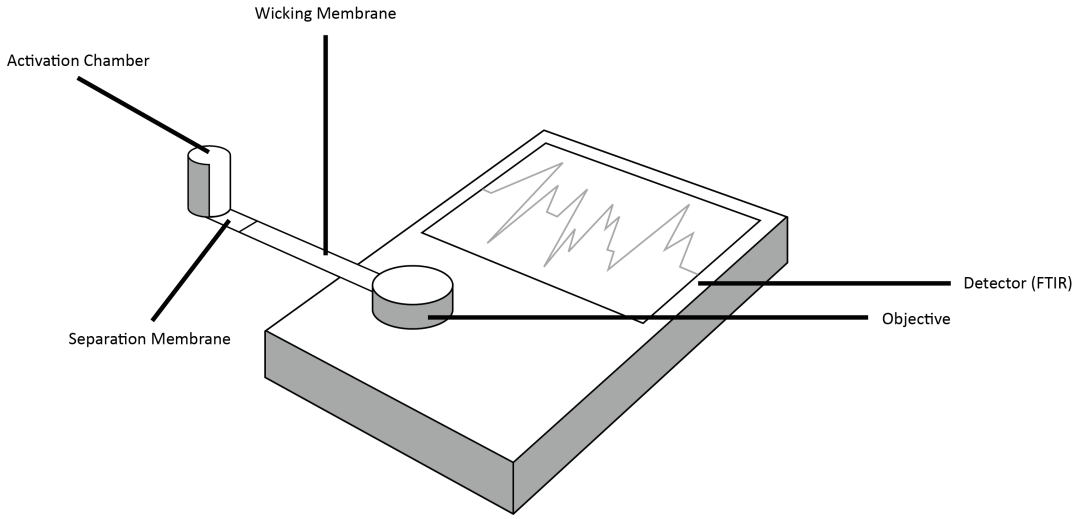

Figure 91:Schematic of the proposed device for clinical testing.

However, in the context of the present study, it has not been possible, primarily for financial reasons that are beyond the scope of the current project, to further develop the technology to a clinically deliverable device. This will form the basis of the the work going forward beyond the current project.

8.2 Summary

1. FTIR is the most appropriate technique that will be employed in the screening test development. It does not require any sample preparation and the results can be obtained within 10 min.
2. Agitation of the blood sample with DEHP plasticised PVC material can be achieved by the development of an activation chamber.
3. Testing the activation chamber with the attached DC vibration motor showed a significant overexpression of IL-6 levels beyond the control values after 30 min with rotor speed 4000 rpm. This confirms the suitability of this approach to activating blood samples.

4. The final design of the proposed device is based upon a combination of proven commercial materials and the application of developed technologies combined with FTIR measurement techniques.
5. Financial constraints limited the development of the proposed technology to proven steps in the cycle, but it was not possible to bring together the components into a formal device. This will be the focus of work going beyond the current project.

Chapter 9: Discussion

9 : Discussion

9.1 Achieved objectives

The achievements of this work in association with the objectives are summarized below;

1. Studying the effect of two common initiators DEHP plasticised PVC and liquid DEHP in the initiation of inflammatory response.
2. Determining the effect of different agitation times in the upregulation of pro-inflammatory cytokines.
3. A clinical study was conducted to investigate the clinical impact of DEHP plasticised PVC and liquid DEHP initiators on the patients' blood samples prior to the surgery. The results were expressed in terms of the rapid pro-inflammatory cytokines (IL-6,TNF-α and CRP).
4. Specifying the most heightened cytokines based on the outcomes from both laboratory and clinical investigations.
5. Specifying the most appropriate initiator to be used in the development process of the screening test technology.
6. Determining the most suitable approach to measure the heightened inflammatory marker levels.
7. Developing the screening test technology which which is the core of this work.

9.2 Why developing a POC screening technology?

The aim from this work was to develop a predictive screening technology that can enable surgeons and clinicians to specify high risk patients prior to open heart surgery. Those patients may develop series of deleterious outcomes such as systemic inflammatory response syndrome (SIRS). SIRS patients required to extend their length of stay in hospital and ITU costing approximately 2000 euro per day. This number is subjected to increase based on the severity of the patient's condition and the complexity of their treatment (Brun-Buisson et al. 2003). Therefore, developing a screening point of care technology to identify those "at risk" patients prior to the surgery may contribute to reducing many unwanted complications and may mitigate the financial burden on the healthcare providers. Once developed, this technology may enable surgeons to stream identified patients to other treatment modalities that do not present such a significant IR risk, for example off-pump approaches, stenting and the use of costly surface modifications and mini-CPB techniques that are not suited to the broad patient community.

9.3 Laboratory and clinical studies

As an early step to achieve the optimal design of the device, it was necessary to determine the effect of the materials / initiators that come in contact with blood during the surgery. From the literature, it is clear that the primary source of inappropriate stimulation of the inflammatory processes is blood contact with the artificial surfaces of the CPB system, in particular the DEHP plasticised PVC tubing structures (Day and Taylor 2005). Therefore, the objective of this work was to utilise the pro-inflammatory properties of the DEHP plasticised PVC as a stimulant for the proposed screening test. This was thought to have two major benefits, firstly that the

pro-inflammatory properties of this material are well defined and secondly that this material is commonly used in CPB systems and was therefore an appropriate stimulant as patient's blood will come into contact with it during clinical practice. Our early results confirmed this association and demonstrated that DEHP plasticised PVC as a suitable initiator of IR for our screening test. We used different weights and different range of volumes of both initiators (DEHP plasticised PVC and liquid DEHP), and two target cytokines for this purpose, IL-6 and TNF-α as there are commonly utilised in clinical practice to evaluate the inflammatory response and have been utilised in previous studies by this group for this purpose (Gourlay et al.2003). Both are upregulated fairly early in the cascade, can be measured using commercial assay kits which will form the basis of the early characterisation studies.

As initiators of the inflammatory response we used ground DEHP plasticised PVC and the plasticiser component of this, liquid DEHP. This group have already described the pro-inflammatory effects of DEHP per seen in previous work (Gourlay et al. 2001), and it was thought that investigating the solid material and the liquid component would give two options for the development of the final screening device. Ultimately it was clear that both initiators were effective in producing the upregulation of IL-6 and TNF-α in isolated bovine blood samples and that there was a clear dose response effect in this. These results confirmed the work of Gourlay, Samartzis et al in previous studies and substantiated the use of these initiators in the proposed device development (Gourlay et al. 2003).

Having determined that there is an appropriate target for measuring the early initiation of inflammatory response to blood/material interaction, and that there was the potential to develop a screening test for this, albeit this was at an early phase of

development, it was thought necessary to carry out a clinical study to investigate whether this test had any clinical validity, and whether there were any other markers, commonly used in the clinical patient journey that would be equally valid. A clinical study of some scale was carried out on 52 patients undergoing elective open-heart surgery for the repair of a number of lesion types. It was thought essential that there should be no selectivity in this patient cohort, other than they should be undergoing first time elective surgery. The purpose of this decision was that we wanted to determine the propensity for these patients to develop a significant IR without stratifying the patients in any way. It is generally accepted that patients who elicit a heightened IR to OHS are beyond pre-surgical prediction using conventional means, for example Euroscoring and age profiling, and our objective was to contrast this unpredictable outcome with our screening system results. Blood samples were taken from these patients' pre-surgery and processed in a similar manner to that employed in our laboratory study. These samples were exposed to DEHP plasticised PVC and liquid DEHP as described and, plasma harvested and processed for cytokine measurement (IL-6, TNF-α and CRP). At the same time, normal patient demographic data and data associated with the clinical course and critically, the clinical outcome in terms of post-operative IR associated complications were harvested for analysis.

After processing of all blood samples in order that the investigators would be truly blinded to the clinical outcome, the patient were splited into two groups for analysis using the post-operative outcome measures, those with IR related complications and those with a normal uncomplicated clinical course. There were 12 patients who exhibited clear signs of post-surgical IR, that led to a more complicated clinical

course. Therefore, around 25% of the patients processed through the study has clear clinical signs of IR complications. This appears somewhat high in terms of modern clinical practice where one might anticipate around 10% in normal practice (Güvener, Korun, and Demirtürk 2015; Kaukonen et al. 2015). However, it should be noted that the CPB system and the protocol for its use was somewhat complex and expansive in terms of exposed surface area, and this may have had an impact. What is clear was that these patients had obvious signs of post-operative IR by the normal clinical measures, varying from moderate to severe when assessed as part of the normal clinical course by clinicians blinded to the focus of the study. Interestingly, our analysis of clinical predictive markers, for example Euroscore showed absolutely no correlation with clinical outcome, and the same applied to other markers considered to be indicative of post-operative complications of IR origin, i.e Age, Gender, CPB time, Cross clamping time etc. The Euroscore data, segmented into low, medium and high risk groups was not found to be a good indicator of post-operative complication rate with a number of false positive and false negative predictions. Analysis of the molecular measurements was however found to be a better predictor of outcome in relation to post-operative IR, with a best fit to the outcome coming from the exposure of blood to ground PVC with IL-6 as the target measurement. TNF-α and CRP were less well suited to the screening test, showing significant numbers of false positive and false negative indications. IL-6 was associated with 66.7% accuracy with only around 3 false positive and 3 false negative indicators. Statistical analysis using regressions analysis of the data demonstrated that DEHP plasticised PVC and IL-6 had a significant association with IR based upon patent outcome analysis. Although there was some misidentification

of outcome in this configuration, in general the level of accuracy observed, with fairly rudimentary techniques, was statistically satisfactory and is considered to be positive in terms of future development. These findings are supported by the current thoughts on IL-6 and its crucial role in the acute phase of inflammation. For example,(Nishimoto et al. 1989; Cruickshank et al. 1990) reported that IL-6 increased before CRP levels in patients undergoing surgery. Also, (Giannoudis et al. 2008) suggested a strong correlation between IL-6 and post-operative outcomes.

Our study suggests that a threshold value for the identification of the propensity for IR in a screening sensor system would enhance the accuracy, if not the sensitivity of the device. The results suggest that a threshold value of around 200 pg/ml for identification of patients who are likely to go on to have a significant IR is valid. Referring back to the post-operative clinical data, we found that 8 out of 12 (66.7%) patients who were identified as having significant post-operative complications of IR origin were above this threshold under pre-operative activated screening.

Having ascertained that the screening process has some clinical validity, the work focussed on developing the technology for the screening device. Critical to this is the determination of the format for the reader and the technology for activating the blood sample and carrying the plasma to the reader for molecular measurement. The activation required the construction of an activation chamber that contains the initiator (ground DEHP plasticised PVC) and this was designed and printed using a 3D printer technique. We utilised technology commonly employed in the telecommunications industry to facilitate the agitation of the blood sample in this chamber in the form of a DC motor, utilised in the mobile phone industry. Testing of this was positive and demonstrated that controlled activation could be achieved using

this technology. The separation and transfer of the plasma from the blood sample will be carried out using commercially available membrane technologies. We had two options for the reader element of the device, standard ELISA and FTIR techniques. Both were investigated during the clinical element of the study, and there was a strong correlation between the results obtained by the two techniques. The choice of the final reader technology is therefore driven by the level of complexity associated with the two approaches. The ELISA technique is a multi-step process, albeit an industry standard for measurement, but it not thought to be suitable for the hand-help POC technique envisaged in this project. The FTIR is simple to apply and readily available as a laboratory tool, and critically is now available in a hand-held device. Going forward, we anticipate that the device will be based upon the use of this hand-held FTIR technology and the agitation and transfer technology developed in the present project. Unfortunately, due to the financial constraints of the current project, we were not able to assemble the final device configuration, but have confidence that this can be carried out without any great difficulty and that this will form a part of the development cycle beyond the current project.

Chapter 10: Conclusion and Future work

10 : Conclusion and future work

10.1 Conclusion

The objective of this work was to investigate the development of a point-of-care screening technology for the determination of the propensity of patients undergoing open-heart surgery to develop a heightened inflammatory response to the procedure. Critically, this screening will take place prior to the surgical procedure in order that those patients identified as heightened responders can be streamed to another mode of intervention. To achieve this, we utilised the known pro-inflammatory properties of DEHP plasticised PVC as an initiator if IR in a sample of blood and conventional ELISA and FTIR measurement as potential measurement tools for the most appropriate marker of the IR. The work conclude that this approach had validity and that of the markers assessed, IL-6 was the most suited. The assessment of clinical samples demonstrated that the screening test was capable of identifying patients known to have gone on to develop significant IR to the procedure with fairly low level false assessments. More work has to be done to further refine the technology and to construct the deliverable POC device for future clinical trials, but the overall outcome of the work suggests that this approach will offer considerable assistance to clinicians in selecting the most appropriate intervention for the treatment of OHS patients through identifying those with a high risk of IR complications prior to surgery. This approach will enable patient stratification in the planning stage and could have a considerable impact on patient morbidity and mortality associated with open heart surgery.

In the context of the present study, a number of objectives were set at the outset of the work. These are listed below, with a commentary on the degree to which these were met.

1. To study the effect of DEHP Plasticised PVC and liquid DEHP in the initiation of inflammatory response on bovine blood and measure the response in terms of IL-6 and TNF-α - **Objective completely met.**
2. To determine the effect of different agitation times in the upregulation of pro-inflammatory cytokines. – **Objective completely met.**
3. To conduct a clinical study to investigate the clinical impact of DEHP plasticised PVC and liquid DEHP initiators on the patients' blood samples prior to the surgery. The results were expressed in terms of the rapid pro-inflammatory cytokines (IL-6,TNF-α and C-reactive protein). – **Objective completely met.**
4. To determine the most appropriate and sensitive pro-inflammatory marker from the three rapid cytokines by using the suitable statistical methodologies. – **Objective completely met.**
5. To specify the most appropriate initiator (DEHP plasticised PVC/liquid DEHP) based on the laboratory and clinical studies. – **Objective completely met.**
6. To specify the most suitable approach to measure the heightened cytokine marker based on using two measurements methods (ELISA and FTIR). – **Objective completely met.**
7. To develop the screening test technology for measuring the heightened upregulation marker. – **Objective partially met.**

10.2 Future work

The future work will include the continuation of the development cycle through to the production of a prototype device for clinical testing. A further clinical trial is also required, preferably of the multi-centre type, to determine the impact and efficacy of the screening process.

Appendices

Appendix A: Bovine (IL-6 and TNF-α) ELISA assay protocol (Source RD bioscience, UK).

Bovine ELISA protocols

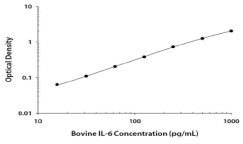
CALCULATION OF RESULTS

Average the duplicate readings for each standard, control, and sample and subtract the average zero standard optical density (O.D.).

Create a standard curve by reducing the data using computer software capable of generating a four parameter logistic (4-PL) curve-fit. As an alternative, construct a standard curve by plotting the mean absorbance for each standard on the y-axis against the concentration on the x-axis and draw a best fit curve through the points on the graph. The data may be linearized by plotting the log of the bovine IL-6 concentrations versus the log of the O.D. and the best fit line can be determined by regression analysis. This procedure will produce an adequate but less precise fit of the data. If samples have been diluted, the concentration read from the standard curve must be multiplied by the dilution factor.

TYPICAL DATA

This standard curve is only for demonstration purposes. A standard curve should be generated for each set of samples assayed.



SPECIFICITY

The following factors prepared at 50 ng/mL were assayed and exhibited no cross-reactivity or interference.

Recombinants:

bovine IL-4	human IL-6
canine IL-6	mouse IL-6
cotton rat IL-6	porcine IL-6
equine IL-6	rat IL-6
feline IL-6	

TECHNICAL HINTS & LIMITATIONS

- We recommend the use of R&D Systems' Reagent Diluent Concentrate 3 (Catalog # DY004) to prepare Reagent Diluent for use in this assay.
- If assaying sample types other than cell culture supernates, each laboratory should develop and validate its own diluent. The diluent must not be used to dilute the Detection Antibody or the Streptavidin-HRP.
- It is important that the Reagent Diluent selected for reconstitution and dilution of the standard reflects the environment of the samples being measured.
- Avoid microbial contamination of reagents and buffers.
- A thorough and consistent wash technique is essential for proper assay performance. Wash Buffer should be dispensed forcefully and removed completely from the wells by aspiration or decanting. Remove any remaining Wash Buffer by inverting the plate and blotting it against clean paper towels.
- Individual results may vary due to differences in technique, plasticware and water sources.
- It is recommended that all standards and samples be assayed in duplicate.
- The use of PBS from tablets may interfere in this assay.

TROUBLESHOOTING

Note: *For more detailed troubleshooting, please visit:*
www.RnDSystems.com/ELISADevelopment

Poor Standard Curve
- Improper reconstitution and/or storage of standard.
- Improper dilution of highest standard and standard curve.
- Incomplete washing and/or aspiration of wells.
- Unequal volumes added to wells/pipetting error.
- Incorrect incubation times or temperatures.

Poor Precision
- Unequal volumes added to wells/pipetting error.
- Incomplete washing and/or aspiration of wells.
- Unequal mixing of reagents.

Low or No color Development
- Inadequate volume of substrate added to wells.
- Incorrect incubation times or temperatures.

DuoSet® ELISA
DEVELOPMENT SYSTEM

Bovine IL-6

Catalog Number: DY8190 (15 plates)

INTENDED USE

For the development of sandwich ELISAs to measure natural and recombinant bovine Interleukin 6 (IL-6). The Reagent Diluent recommended may be suitable for most cell culture supernate, serum, and plasma samples. The Reagent Diluent selected for use can alter the performance of an immunoassay. Reagent Diluent optimization for samples with complex matrices such as serum and plasma, may improve their performance in this assay.

This kit contains sufficient materials to run ELISAs on at least fifteen 96 well plates, provided the following conditions are met:
- The reagents are prepared as described in this package insert.
- The assay is run as described in the General ELISA Protocol.
- The recommended microplates, buffers, diluents, substrates, and solutions are used.

This package insert must be read in its entirety before using this product.
Refer to the Certificate of Analysis for component concentrations as they may vary.
For research use only. Not for use in diagnostic procedures.

R&D SYSTEMS a bio-techne brand

OTHER MATERIALS & SOLUTIONS REQUIRED

DuoSet Ancillary Reagent Kit 3 (5 plates):
(R&D Systems, Catalog # DY009) containing 96 well microplates, plate sealers, substrate solution, stop solution, plate coating buffer (PBS), wash buffer, and Reagent Diluent Concentrate 3.

The components listed above may be purchased separately:

96 well microplates: (R&D Systems, Catalog # DY990).

Plate Sealers: (R&D Systems, Catalog # DY992).

PBS: 137 mM NaCl, 2.7 mM KCl, 8.1 mM Na_2HPO_4, 1.5 mM KH_2PO_4, pH 7.2-7.4, 0.2 µm filtered (R&D Systems, Catalog # DY006).

Wash Buffer: 0.05% Tween® 20 in PBS, pH 7.2-7.4
(R&D Systems, Catalog # WA126).

Reagent Diluent: 5% Tween 20 in PBS, pH 7.2-7.4, 0.2 µm filtered.
(R&D Systems Catalog # DY004).

Substrate Solution: 1:1 mixture of Color Reagent A (H_2O_2) and Color Reagent B (Tetramethylbenzidine) (R&D Systems, Catalog # DY999).

Stop Solution: 2 N H_2SO_4 (R&D Systems, Catalog # DY994).

PRECAUTIONS

Some components in this kit contain ProClin® which may cause an allergic skin reaction. Avoid breathing mist.

The Stop Solution suggested for use with this kit is an acid solution.

The Color Reagent B suggested for use with this kit may cause skin, eye, and respiratory irritation. Avoid breathing fumes.

Wear protective gloves, clothing, eye, and face protection. Wash hands thoroughly after handling. Please refer to the MSDS on our website prior to use.

CALIBRATION

This DuoSet is calibrated against a highly purified *E. coli*-expressed recombinant bovine IL-6 produced at R&D Systems.

MATERIALS PROVIDED & STORAGE CONDITIONS

Store the unopened kit at 2-8 °C. Do not use past kit expiration date.

DESCRIPTION	PART #	# VIALS	STORAGE OF OPENED/ RECONSTITUTED MATERIAL
Bovine IL-6 Capture Antibody	844129	1 vial	Refer to the lot-specific Certificate of Analysis (C of A) for storage conditions.
Bovine IL-6 Detection Antibody	844130	1 vial	
Bovine IL-6 Standard	844131	3 vials	
Streptavidin-HRP	890803	1 vial	

REAGENT PREPARATION

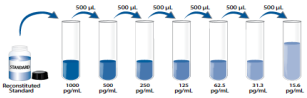
Bring all reagents to room temperature before use. Allow all components to sit for a minimum of 15 minutes with gentle agitation after initial reconstitution. Working dilutions should be prepared and used immediately.

Streptavidin-HRP: 1.0 mL of streptavidin conjugated to horseradish-peroxidase. Dilute to the working concentration specified on the vial label using Reagent Diluent.

Mouse Anti-Bovine IL-6 Capture Antibody: Refer to the lot-specific C of A for amount supplied. Reconstitute each vial with 1.0 mL of PBS. Dilute in PBS without carrier protein to the working concentration indicated on the C of A.

Biontinylated Mouse Anti-Bovine IL-6 Detection Antibody: Refer to the lot-specific C of A for amount supplied. Reconstitute each vial with 1.0 mL of Reagent Diluent. Dilute in Reagent Diluent to the working concentration indicated on the C of A.

Recombinant Bovine IL-6 Standard: Refer to the lot-specific C of A for amount supplied. Reconstitute each vial with 0.5 mL of Reagent Diluent. A seven point standard curve using 2-fold serial dilutions in Reagent Diluent is recommended. Prepare 1000 µL of high standard per plate assayed at the concentration indicated on the C of A.



GENERAL ELISA PROTOCOL

Plate Preparation

1. Dilute the Capture Antibody to the working concentration in PBS without carrier protein. Immediately coat a 96-well microplate with 100 µL per well of the diluted Capture Antibody. Seal the plate and incubate overnight at room temperature.
2. Aspirate each well and wash with Wash Buffer, repeating the process two times for a total of three washes. Wash by filling each well with Wash Buffer (400 µL) using a squirt bottle, manifold dispenser, or autowasher. Complete removal of liquid at each step is essential for good performance. After the last wash, remove any remaining Wash Buffer by aspirating or by inverting the plate and blotting it against clean paper towels.
3. Block plates by adding 300 µL of Reagent Diluent to each well. Incubate at room temperature for a minimum of 1 hour.
4. Repeat the aspiration/wash as in step 2. The plates are now ready for sample addition.

Assay Procedure

1. Add 100 µL of sample or standards in Reagent Diluent, or an appropriate diluent, per well. Cover with an adhesive strip and incubate 2 hours at room temperature.
2. Repeat the aspiration/wash as in step 2 of Plate Preparation.
3. Add 100 µL of the Detection Antibody, diluted in Reagent Diluent, to each well. Cover with a new adhesive strip and incubate 2 hours at room temperature.
4. Repeat the aspiration/wash as in step 2 of Plate Preparation.
5. Add 100 µL of the working dilution of Streptavidin-HRP to each well. Cover the plate and incubate for 20 minutes at room temperature. Avoid placing the plate in direct light.
6. Repeat the aspiration/wash as in step 2.
7. Add 100 µL of Substrate Solution to each well. Incubate for 20 minutes at room temperature. Avoid placing the plate in direct light.
8. Add 50 µL of Stop Solution to each well. Gently tap the plate to ensure thorough mixing.
9. Determine the optical density of each well immediately, using a microplate reader set to 450 nm. If wavelength correction is available, set to 540 nm or 570 nm. If wavelength correction is not available, subtract readings at 540 nm or 570 nm from the readings at 450 nm. This subtraction will correct for optical imperfections in the plate. Readings made directly at 450 nm without correction may be higher and less accurate.

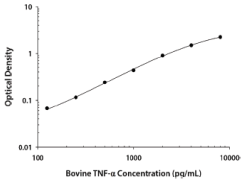
CALCULATION OF RESULTS

Average the duplicate readings for each standard, control, and sample and subtract the average zero standard optical density (O.D.).

Create a standard curve by reducing the data using computer software capable of generating a four parameter logistic (4-PL) curve-fit. As an alternative, construct a standard curve by plotting the mean absorbance for each standard on the y-axis against the concentration on the x-axis and draw a best fit curve through the points on the graph. The data may be linearized by plotting the log of the bovine TNF-α concentrations versus the log of the O.D. and the best fit line can be determined by regression analysis. This procedure will produce an adequate but less precise fit of the data. If samples have been diluted, the concentration read from the standard curve must be multiplied by the dilution factor.

TYPICAL DATA

This standard curve is only for demonstration purposes. A standard curve should be generated for each set of samples assayed.



SPECIFICITY

The following factors prepared at 50 ng/mL were assayed and exhibited no cross-reactivity or interference.

Recombinants:
cotton rat TNF-α
equine TNF-α
feline TNF-α
human TNF-α
mouse TNF-α
porcine TNF-α
rat TNF-α
rhesus macaque TNF-α

Recombinant canine TNF-α does not cross-react in this assay but does interfere at concentrations > 50 ng/mL.

TECHNICAL HINTS & LIMITATIONS

- We recommend the use of R&D Systems' Reagent Diluent Concentrate 3 (Catalog # DY004) to prepare Reagent Diluent for use in this assay.
- If assaying sample types other than cell culture supernates, each laboratory should develop and validate its own diluent. The diluent must not be used to dilute the Detection Antibody or the Streptavidin-HRP.
- It is important that the Reagent Diluent selected for dilution of the standard reflects the environment of the samples being measured.
- Avoid microbial contamination of reagents and buffers.
- A thorough and consistent wash technique is essential for proper assay performance. Wash Buffer should be dispensed forcefully and removed completely from the wells by aspiration or decanting. Remove any remaining Wash Buffer by inverting the plate and blotting it against clean paper towels.
- Individual results may vary due to differences in technique, plasticware and water sources.
- It is recommended that all standards and samples be assayed in duplicate.
- The use of PBS from tablets may interfere in this assay.

CALIBRATION

This DuoSet is calibrated against a highly purified *E. coli*-expressed recombinant bovine TNF-α produced at R&D Systems.

MATERIALS PROVIDED & STORAGE CONDITIONS

Store the unopened kit at 2-8 °C. Do not use past kit expiration date.

DESCRIPTION	PART #	# VIALS	STORAGE OF OPENED/ RECONSTITUTED MATERIAL
Bovine TNF-α Capture Antibody	842628	1 vial	Refer to the lot-specific Certificate of Analysis (C of A) for storage conditions.
Bovine TNF-α Detection Antibody	842629	1 vial	
Bovine TNF-α Standard	842630	3 vials	
Streptavidin-HRP	890803	1 vial	

REAGENT PREPARATION

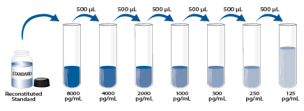
Bring all reagents to room temperature before use. Allow all components to sit for a minimum of 15 minutes with gentle agitation after initial reconstitution. Working dilutions should be prepared and used immediately, unless otherwise noted.

Streptavidin-HRP: 1.0 mL of streptavidin conjugated to horseradish-peroxidase. Dilute to the working concentration specified on the vial label using Reagent Diluent.

Goat Anti-Bovine TNF-α Capture Antibody: Refer to the lot-specific C of A for amount supplied. Reconstitute with 1.0 mL of PBS. Dilute in PBS without carrier protein to the working concentration indicated on the C of A.

Biotinylated Goat Anti-Bovine TNF-α Detection Antibody: Refer to the lot-specific C of A for amount supplied. Reconstitute with 1.0 mL of Reagent Diluent. Dilute in Reagent Diluent with 2% heat inactivated normal goat serum (NGS) to the working concentration indicated on the C of A. Prepare 1-2 hours prior to use.

Recombinant Bovine TNF-α Standard: Refer to the lot-specific C of A for amount supplied. Reconstitute each vial with 0.5 mL of Reagent Diluent. A seven point standard curve using 2-fold serial dilutions in Reagent Diluent is recommended. Prepare 1000 µL of high standard per plate assayed at the concentration indicated on the C of A.



GENERAL ELISA PROTOCOL

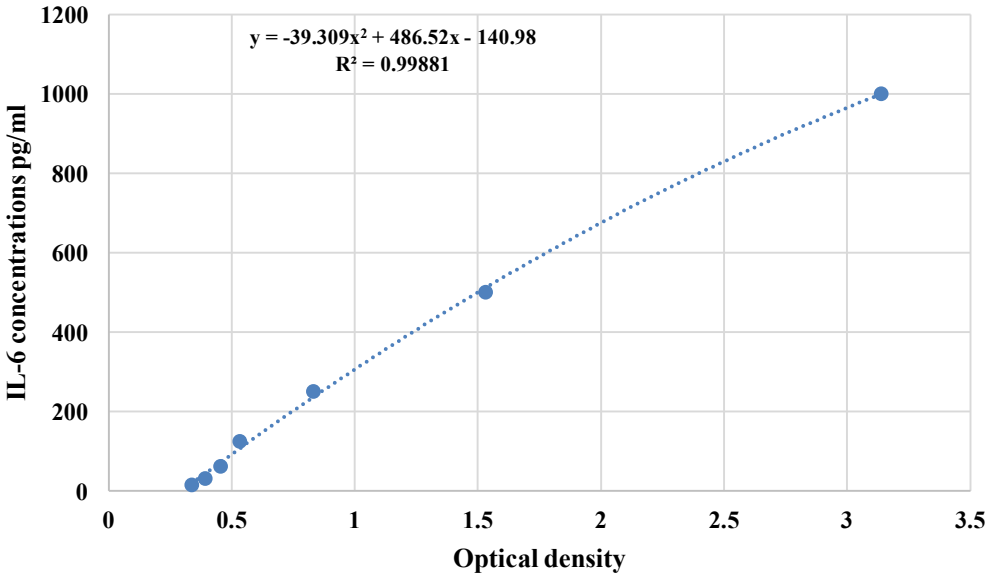
Plate Preparation

1. Dilute the Capture Antibody to the working concentration in PBS without carrier protein. Immediately coat a 96-well microplate with 100 µL per well of the diluted Capture Antibody. Seal the plate and incubate overnight at room temperature.
2. Aspirate each well and wash with Wash Buffer, repeating the process two times for a total of three washes. Wash by filling each well with Wash Buffer (400 µL) using a squirt bottle, manifold dispenser, or autowasher. Complete removal of liquid at each step is essential for good performance. After the last wash, remove any remaining Wash Buffer by aspirating or by inverting the plate and blotting it against clean paper towels.
3. Block plates by adding 300 µL of Reagent Diluent to each well. Incubate at room temperature for a minimum of 1 hour.
4. Repeat the aspiration/wash as in step 2. The plates are now ready for sample addition.

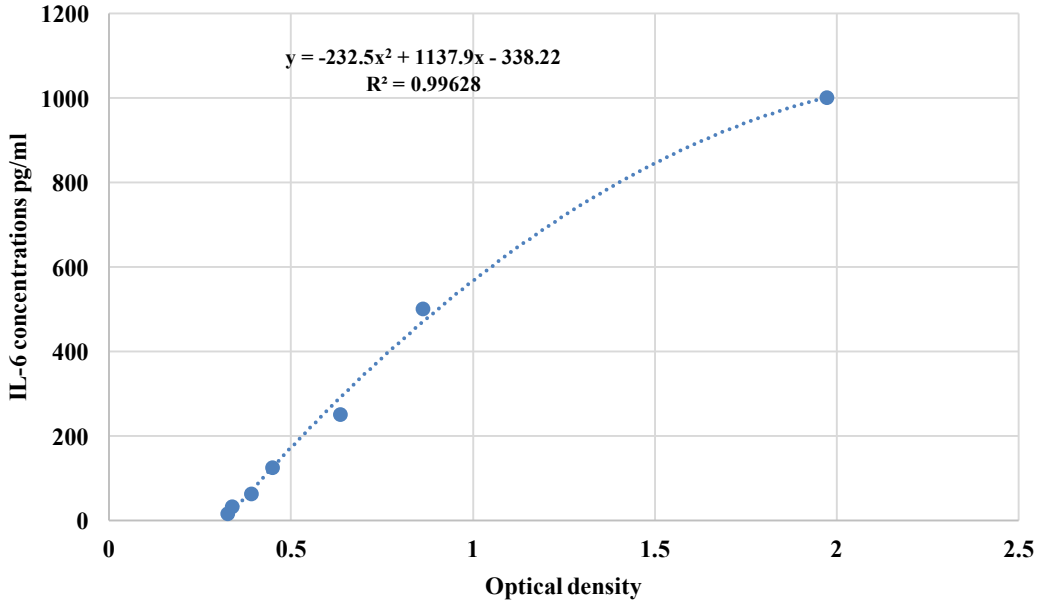
Assay Procedure

1. Add 100 µL of sample or standards in Reagent Diluent, or an appropriate diluent, per well. Cover with an adhesive strip and incubate 2 hours at room temperature.
2. Repeat the aspiration/wash as in step 2 of Plate Preparation.
3. Add 100 µL of the Detection Antibody, diluted in Reagent Diluent with NGS, to each well. Cover with a new adhesive strip and incubate 2 hours at room temperature.
4. Repeat the aspiration/wash as in step 2 of Plate Preparation.
5. Add 100 µL of the working dilution of Streptavidin-HRP to each well. Cover the plate and incubate for 20 minutes at room temperature. Avoid placing the plate in direct light.
6. Repeat the aspiration/wash as in step 2.
7. Add 100 µL of Substrate Solution to each well. Incubate for 20 minutes at room temperature. Avoid placing the plate in direct light.
8. Add 50 µL of Stop Solution to each well. Gently tap the plate to ensure thorough mixing.
9. Determine the optical density of each well immediately, using a microplate reader set to 450 nm. If wavelength correction is available, set to 540 nm or 570 nm. If wavelength correction is not available, subtract readings at 540 nm or 570 nm from the readings at 450 nm. This subtraction will correct for optical imperfections in the plate. Readings made directly at 450 nm without correction may be higher and less accurate.

Appendix B: Bovine IL-6 standard curves

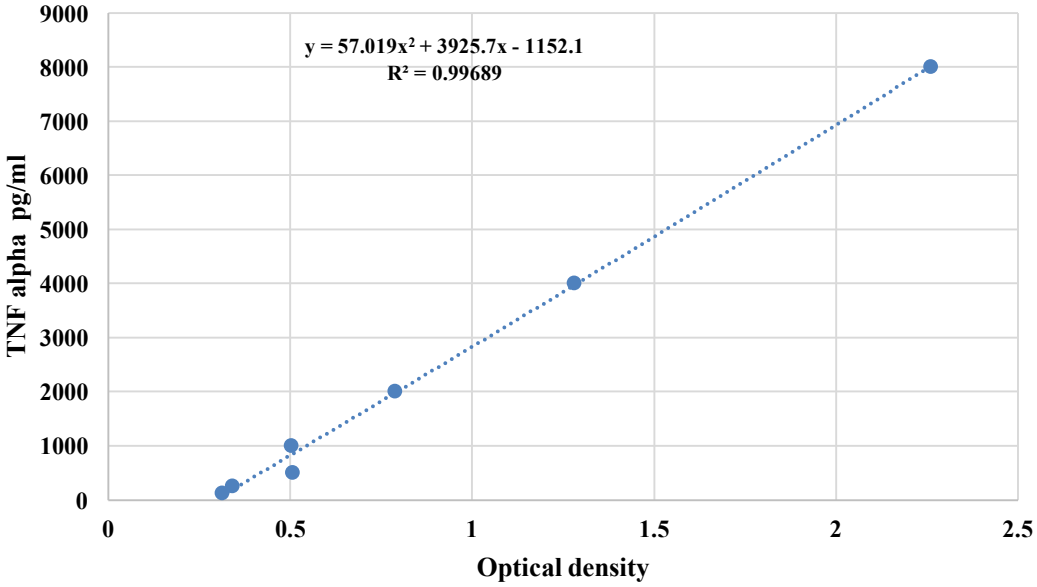


IL-6 standard curve (ELISA1)

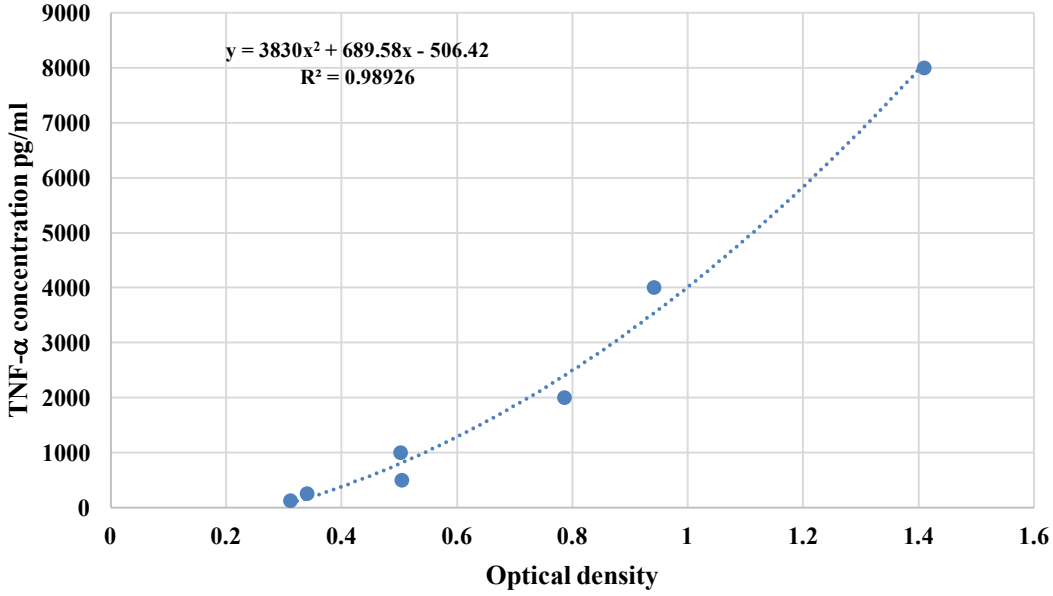


IL-6 standard curve (ELISA 3)

Appendix C: Bovine TNF-α standard curves



TNF-α standard curve (ELISA 1)



TNF-α standard curve (ELISA 3)

Appendix D: Human ELISA protocols (IL-6,TNF-α-C-reactive protein)

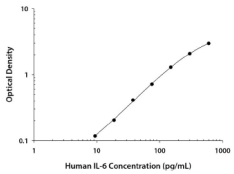
CALCULATION OF RESULTS

Average the duplicate readings for each standard, control, and sample and subtract the average zero standard optical density (O.D.).

Create a standard curve by reducing the data using computer software capable of generating a four parameter logistic (4-PL) curve-fit. As an alternative, construct a standard curve by plotting the mean absorbance for each standard on the y-axis against the concentration on the x-axis and draw a best fit curve through the points on the graph. The data may be linearized by plotting the log of the human IL-6 concentrations versus the log of the O.D. and the best fit line can be determined by regression analysis. This procedure will produce an adequate but less precise fit of the data. If samples have been diluted, the concentration read from the standard curve must be multiplied by the dilution factor.

TYPICAL DATA

This standard curve is only for demonstration purposes. A standard curve should be generated for each set of samples assayed.



SPECIFICITY

The following factors prepared at 50 ng/mL were assayed and exhibited no cross-reactivity or interference.

Recombinant human:
CNTF
G-CSF
gp130
IL-6 R
IL-11
IL-12
LIF
LIF R
OSM

Recombinant mouse:
IL-6
IL-11
IL-12

Recombinant rat:
CNTF

TECHNICAL HINTS & LIMITATIONS

- We recommend the use of R&D Systems' Reagent Diluent Concentrate 2 (Catalog # DY995) to prepare Reagent Diluent for use in this assay.
- The use of high quality Bovine Serum Albumin (BSA) for the Reagent Diluent is crucial for the optimum performance of the DuoSet ELISA Development kit. Impurities such as proteases, binding proteins, soluble receptors or other interfering substances can be found to varying degrees in virtually all BSA preparations and can inhibit or interfere with the detection of certain analytes. If the standard curve appears suppressed, consider evaluating a different preparation of BSA.
- It is suggested to start Reagent Diluent optimization for serum and plasma samples by using PBS supplemented with 10-50% animal serum. Do not use buffers with animal serum to reconstitute or dilute the Detection Antibody or Streptavidin-HRP.
- It is important that the Reagent Diluent selected for dilution of the standard reflects the environment of the samples being measured.
- Avoid microbial contamination of reagents and buffers.
- A thorough and consistent wash technique is essential for proper assay performance. Wash Buffer should be dispensed forcefully and removed completely from the wells by aspiration or decanting. Remove any remaining Wash Buffer by inverting the plate and blotting it against clean paper towels.
- Individual results may vary due to differences in technique, plasticware and water sources.
- It is recommended that all standards and samples be assayed in duplicate.
- The use of PBS from tablets may interfere in this assay.

TROUBLESHOOTING

Note: *For more detailed troubleshooting, please visit:*
www.RnDSystems.com/ELISADevelopment

Poor Standard Curve
- Impure BSA used for Reagent Diluent preparation.
- Improper reconstitution and/or storage of standard.
- Improper dilution of highest standard and standard curve.
- Incomplete washing and/or aspiration of wells.
- Unequal volumes added to wells/pipetting error.
- Incorrect incubation times or temperatures.

Poor Precision
- Unequal volumes added to wells/pipetting error.
- Incomplete washing and/or aspiration of wells.
- Unequal mixing of reagents.

Low or No Color Development
- Inadequate volume of substrate added to wells.
- Incorrect incubation times or temperatures.
- Impure BSA used for Reagent Diluent preparation.

DuoSet® ELISA
DEVELOPMENT SYSTEM

Human IL-6

Catalog Numbers: DY206-05 (5 plates)
DY206 (15 plates)

INTENDED USE

For the development of sandwich ELISAs to measure natural and recombinant human Interleukin 6 (IL-6). The Reagent Diluent recommended may be suitable for most cell culture supernate, serum, and plasma samples. The Reagent Diluent selected for use can alter the performance of an immunoassay. Reagent Diluent optimization for samples with complex matrices such as serum and plasma, may improve their performance in this assay.

This kit contains sufficient materials to run ELISAs on at least five 96 well plates, provided the following conditions are met:
- The reagents are prepared as described in this package insert.
- The assay is run as described in the General ELISA Protocol.
- The recommended microplates, buffers, diluents, substrates, and solutions are used.

This package insert must be read in its entirety before using this product.
Refer to the Certificate of Analysis for component concentrations as they may vary.
For research use only. Not for use in diagnostic procedures.

OTHER MATERIALS & SOLUTIONS REQUIRED

DuoSet Ancillary Reagent Pack 2 (5 plates):
(R&D Systems, Catalog # DY008) containing 96 well microplates, plate sealers, substrate solution, stop solution, plate coating buffer (PBS), wash buffer, and Reagent Diluent 2.

The components listed above may be purchased separately:

96 well microplates: (R&D Systems, Catalog # DY990).

Plate sealers: (R&D Systems, Catalog # DY992).

PBS: 137 mM NaCl, 2.7 mM KCl, 8.1 mM Na_2HPO_4, 1.5 mM KH_2PO_4, pH 7.2-7.4, 0.2 µm filtered (R&D Systems, Catalog # DY006).

Wash Buffer: 0.05% Tween® 20 in PBS, pH 7.2-7.4
(R&D Systems, Catalog # WA126).

Reagent Diluent: 1% BSA in PBS, pH 7.2-7.4, 0.2 µm filtered
(R&D Systems, Catalog # DY995).
Quality of BSA is critical (see Technical Hints).

Substrate Solution: 1:1 mixture of Color Reagent A (H_2O_2) and Color Reagent B (Tetramethylbenzidine) (R&D Systems, Catalog # DY999).

Stop Solution: 2 N H_2SO_4 (R&D Systems, Catalog # DY994).

PRECAUTIONS

Some components in this kit contain ProClin® which may cause an allergic skin reaction. Avoid breathing mist.

The Stop Solution suggested for use with this kit is an acid solution.

The Color Reagent B suggested for use with this kit may cause skin, eye, and respiratory irritation. Avoid breathing fumes.

Wear protective gloves, clothing, eye, and face protection. Wash hands thoroughly after handling. Please refer to the MSDS on our website prior to use.

CALIBRATION

This DuoSet is calibrated against a highly purified *E. coli*-expressed recombinant human IL-6 produced at R&D Systems.

MATERIALS PROVIDED & STORAGE CONDITIONS

Store the unopened kit at 2-8 °C. Do not use past kit expiration date.

DESCRIPTION	PART #	CATALOG # DY206-05	CATALOG # DY206	STORAGE OF OPENED/ RECONSTITUTED MATERIAL
Human IL-6 Capture Antibody	840113	1 vial	3 vials	Refer to the lot-specific Certificate of Analysis (C of A) for storage conditions.
Human IL-6 Detection Antibody	840114	1 vial	3 vials

- The recommended microplates, buffers, diluents, substrates, and solutions are used.

This package insert must be read in its entirety before using this product.
Refer to the Certificate of Analysis for component concentrations as they may vary.
For research use only. Not for use in diagnostic procedures.

OTHER MATERIALS & SOLUTIONS REQUIRED

DuoSet Ancillary Reagent Kit 2 (5 plates):
(R&D Systems, Catalog # DY008) containing 96 well microplates, plate sealers, substrate solution, stop solution, plate coating buffer (PBS), wash buffer, and Reagent Diluent Concentrate 2.

The components listed above may be purchased separately:

96 well microplates: (R&D Systems, Catalog # DY990).

Plate Sealers: (R&D Systems, Catalog # DY992).

PBS: 137 mM NaCl, 2.7 mM KCl, 8.1 mM Na_2HPO_4, 1.5 mM KH_2PO_4, pH 7.2-7.4, 0.2 µm filtered (R&D Systems, Catalog # DY006).

Wash Buffer: 0.05% Tween® 20 in PBS, pH 7.2-7.4
(R&D Systems, Catalog # WA126).

Reagent Diluent: 1% BSA in PBS, pH 7.2-7.4, 0.2 µm filtered
(R&D Systems, Catalog # DY995).
Quality of BSA is critical (see Technical Hints).

Substrate Solution: 1:1 mixture of Color Reagent A (H_2O_2) and Color Reagent B (Tetramethylbenzidine) (R&D Systems, Catalog # DY999).

Stop Solution: 2 N H_2SO_4 (R&D Systems, Catalog # DY994).

PRECAUTIONS

Some components in this kit contain ProClin® which may cause an allergic skin reaction. Avoid breathing mist.

The Stop Solution suggested for use with this kit is an acid solution.

The Color Reagent B suggested for use with this kit may cause skin, eye, and respiratory irritation. Avoid breathing fumes.

Wear protective gloves, clothing, eye, and face protection. Wash hands thoroughly after handling. Please refer to the MSDS on our website prior to use.

CALIBRATION

This DuoSet is calibrated against a highly purified NS0-expressed recombinant human CRP produced at R&D Systems.

MATERIALS PROVIDED & STORAGE CONDITIONS

Store the unopened kit at 2-8 °C. Do not use past kit expiration date.

DESCRIPTION	PART #	# VIALS	STORAGE OF OPENED/ RECONSTITUTED MATERIAL
Human CRP Capture Antibody	842676	1 vial	Refer to the lot-specific Certificate of Analysis (C of A) for storage conditions.
Human CRP Detection Antibody	842677	1 vial	
Human CRP Standard	842678	1 vial	
Streptavidin-HRP	890803	1 vial	

REAGENT PREPARATION

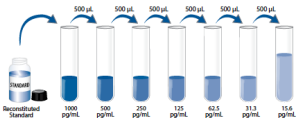
Bring all reagents to room temperature before use. Allow all components to sit for a minimum of 15 minutes with gentle agitation after initial reconstitution. Working dilutions should be prepared and used immediately.

Streptavidin-HRP: 1.0 mL of streptavidin conjugated to horseradish-peroxidase. Dilute to the working concentration specified on the vial label using Reagent Diluent.

Mouse Anti-Human CRP Capture Antibody: Refer to the lot-specific C of A for amount supplied. Reconstitute with 1.0 mL of PBS. Dilute in PBS without carrier protein to the working concentration indicated on the C of A.

Biotinylated Mouse Anti-Human CRP Detection Antibody: Refer to the lot-specific C of A for amount supplied. Reconstitute with 1.0 mL of Reagent Diluent. Dilute in Reagent Diluent to the working concentration indicated on the C of A.

Recombinant Human CRP Standard: Refer to the lot-specific C of A for amount supplied. Reconstitute with 0.5 mL of Reagent Diluent. A seven point standard curve using 2-fold serial dilutions in Reagent Diluent is recommended. Prepare 1000 µL of high standard per plate assayed at the concentration indicated on the C of A.



GENERAL ELISA PROTOCOL

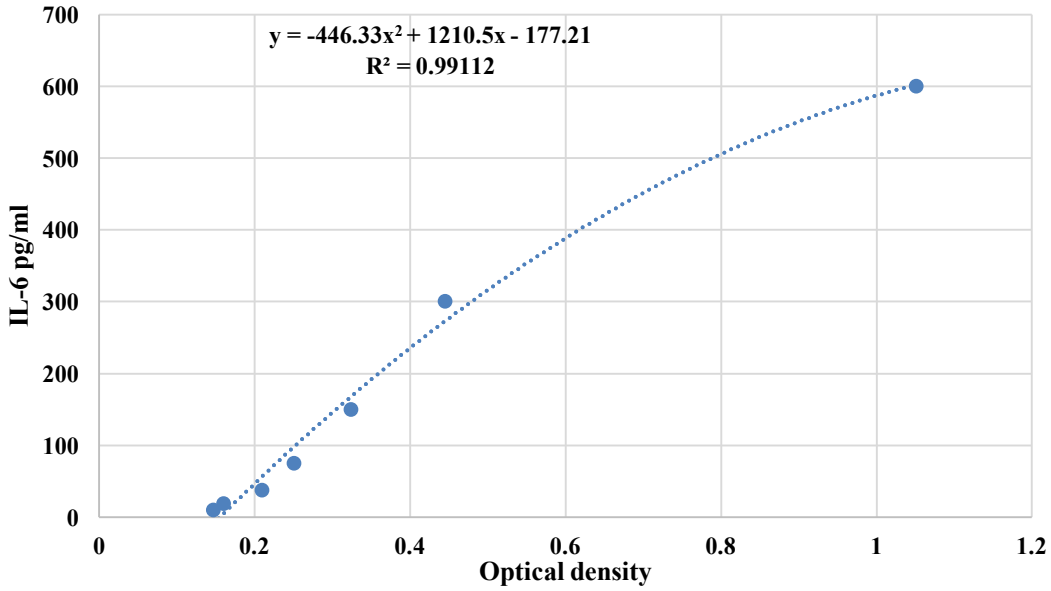
Plate Preparation

1. Dilute the Capture Antibody to the working concentration in PBS without carrier protein. Immediately coat a 96-well microplate with 100 µL per well of the diluted Capture Antibody. Seal the plate and incubate overnight at room temperature.
2. Aspirate each well and wash with Wash Buffer, repeating the process two times for a total of three washes. Wash by filling each well with Wash Buffer (400 µL) using a squirt bottle, manifold dispenser, or autowasher. Complete removal of liquid at each step is essential for good performance. After the last wash, remove any remaining Wash Buffer by aspirating or by inverting the plate and blotting it against clean paper towels.
3. Block plates by adding 300 µL of Reagent Diluent to each well. Incubate at room temperature for a minimum of 1 hour.
4. Repeat the aspiration/wash as in step 2. The plates are now ready for sample addition.

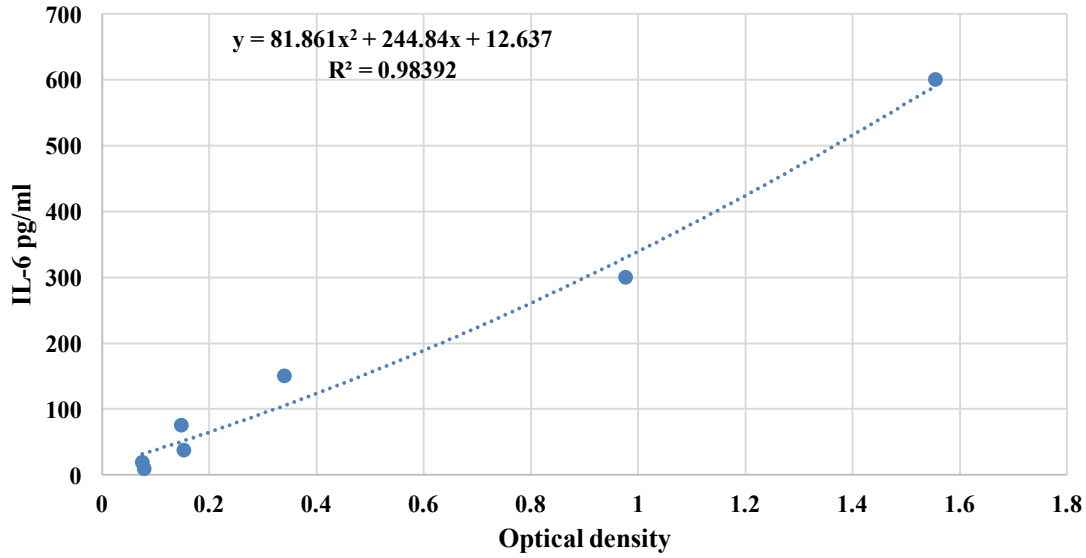
Assay Procedure

1. Add 100 µL of sample or standards in Reagent Diluent, or an appropriate diluent, per well. Cover with an adhesive strip and incubate 2 hours at room temperature.
2. Repeat the aspiration/wash as in step 2 of Plate Preparation.
3. Add 100 µL of the Detection Antibody, diluted in Reagent Diluent, to each well. Cover with a new adhesive strip and incubate 2 hours at room temperature.
4. Repeat the aspiration/wash as in step 2 of Plate Preparation.
5. Add 100 µL of the working dilution of Streptavidin-HRP to each well. Cover the plate and incubate for 20 minutes at room temperature. Avoid placing the plate in direct light.
6. Repeat the aspiration/wash as in step 2.
7. Add 100 µL of Substrate Solution to each well. Incubate for 20 minutes at room temperature. Avoid placing the plate in direct light.
8. Add 50 µL of Stop Solution to each well. Gently tap the plate to ensure thorough mixing.
9. Determine the optical density of each well immediately, using a microplate reader set to 450 nm. If wavelength correction is available, set to 540 nm or 570 nm. If wavelength correction is not available, subtract readings at 540 nm or 570 nm from the readings at 450 nm. This subtraction will correct for optical imperfections in the plate. Readings made directly at 450 nm without correction may be higher and less accurate.

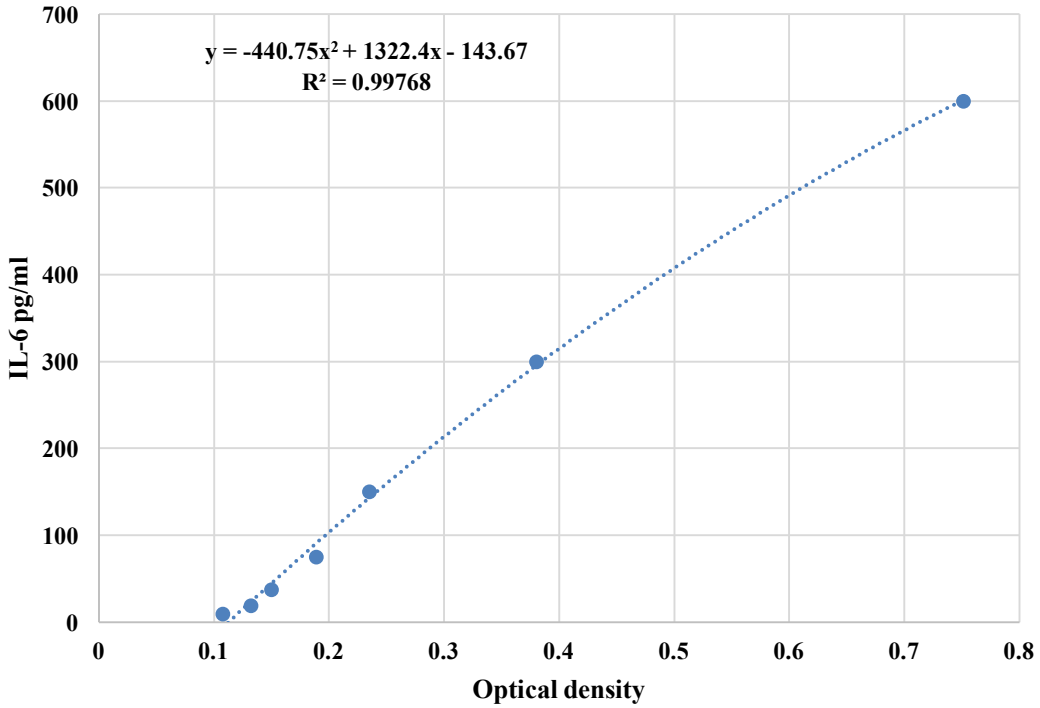
Appendix E: Human IL-6 standard curves



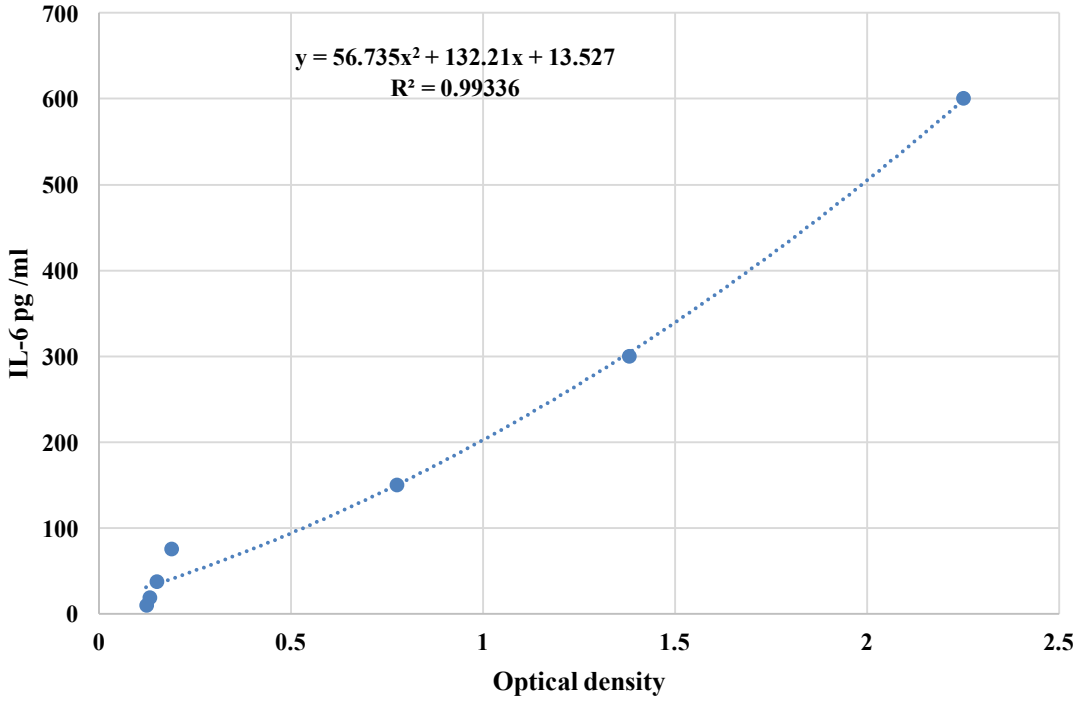
IL-6 standard curve (ELISA 1) for patients (P1-P20)



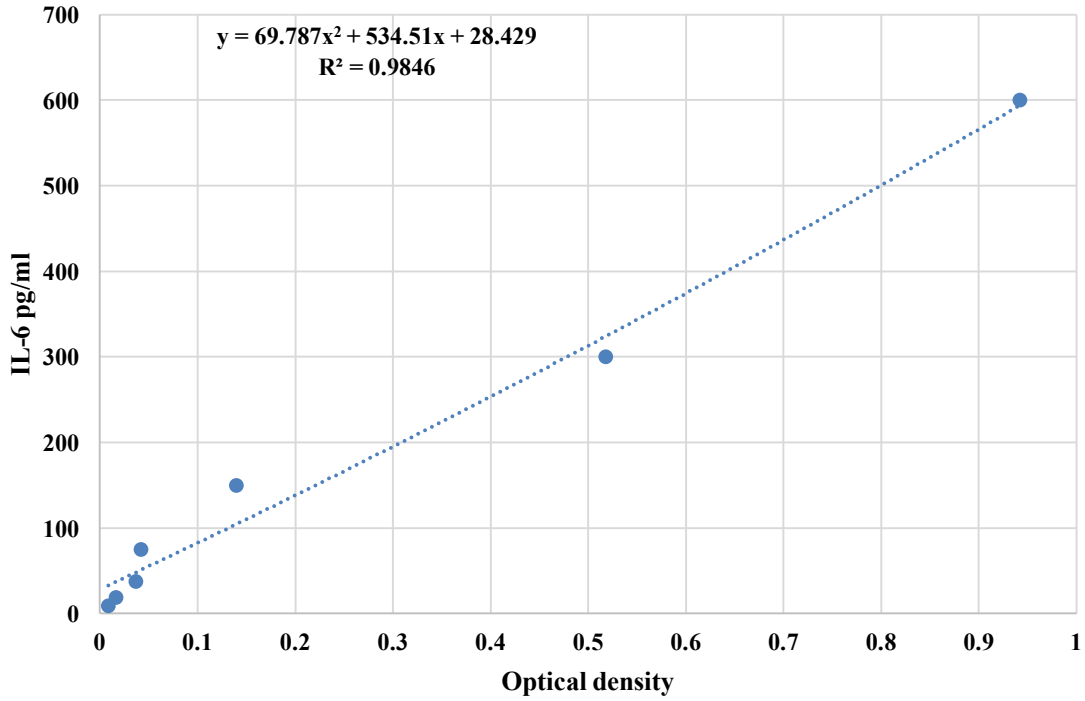
IL-6 standard curve (ELISA 2) for patients (P1-P20)



standard curve (ELISA 1) for patients (P21-P40)

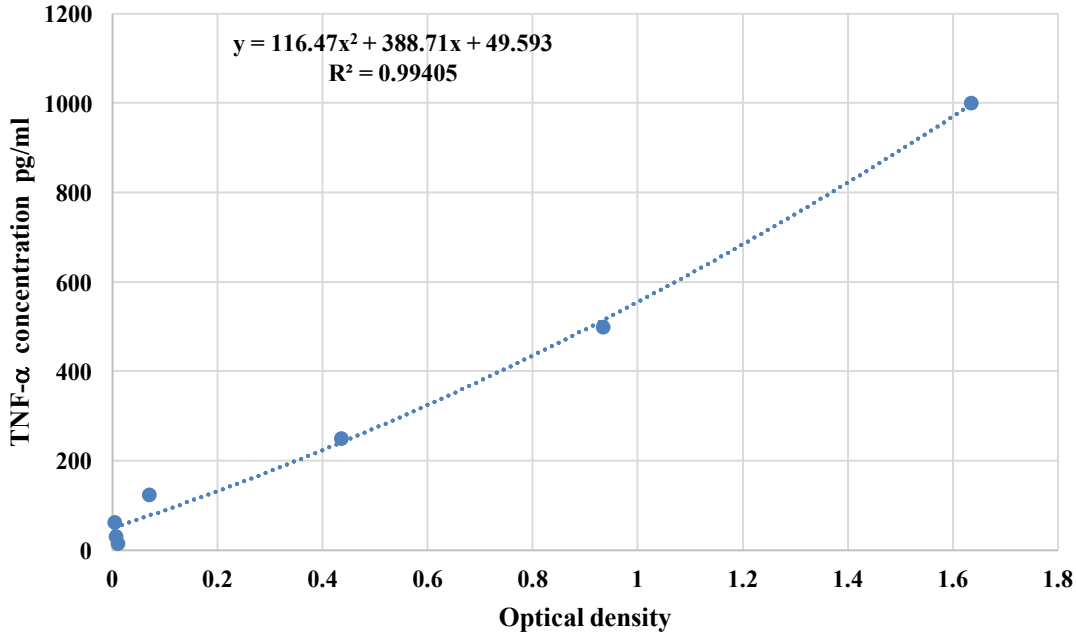


IL-6 standard Curve (ELISA 2) for patients (P21-P40).

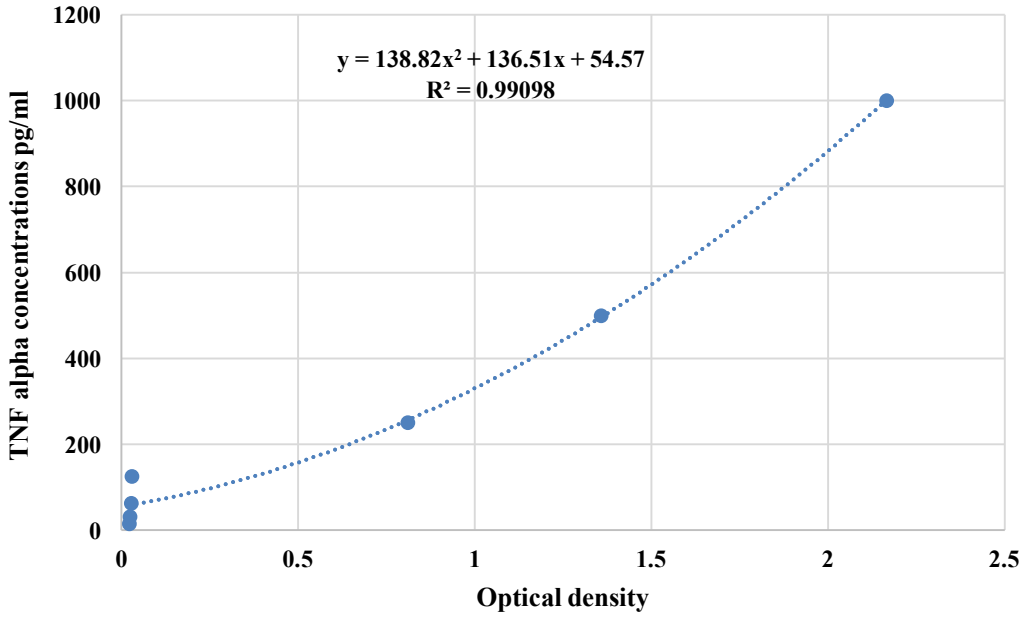


IL-6 standard curve (ELISA 1) for patients (P41-P52)

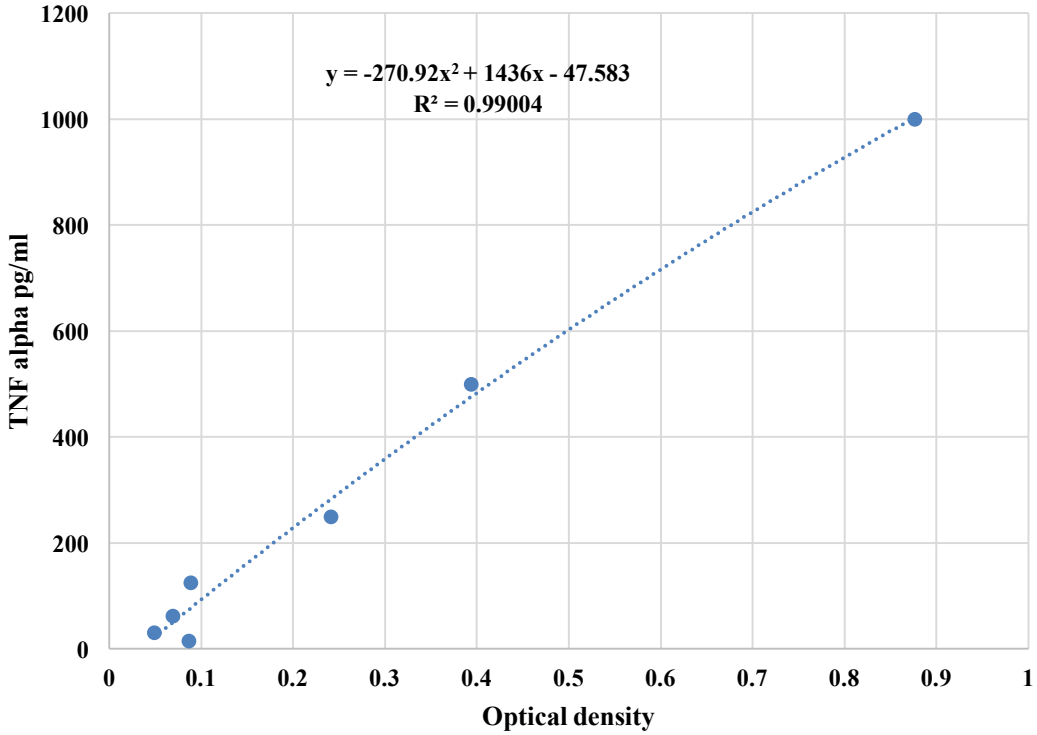
Appendix F: TNF-α standard curves for all patients' samples .



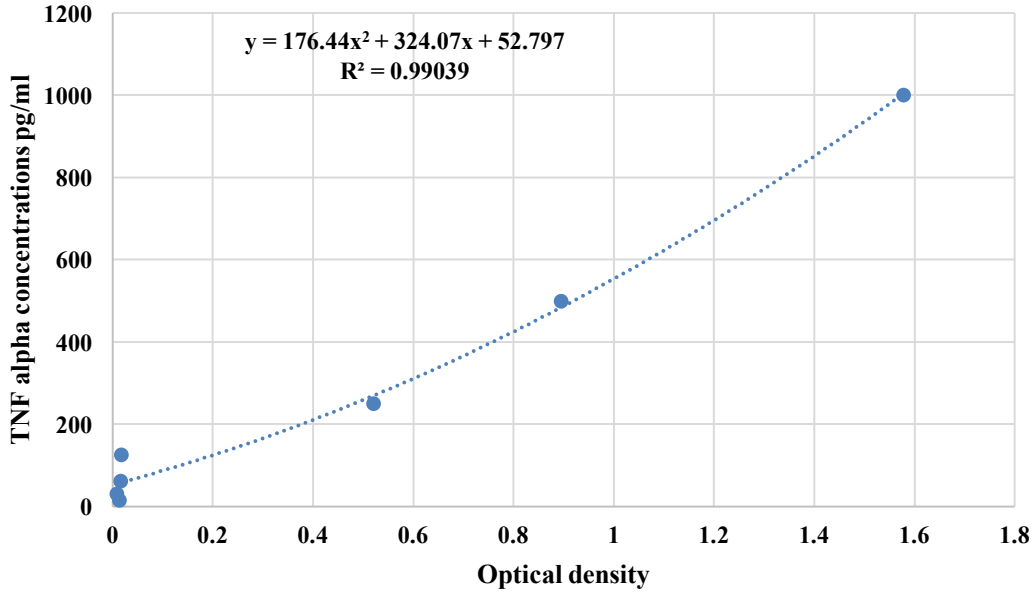
TNF-α standard curve (ELISA 1) for patients (P1-P20)



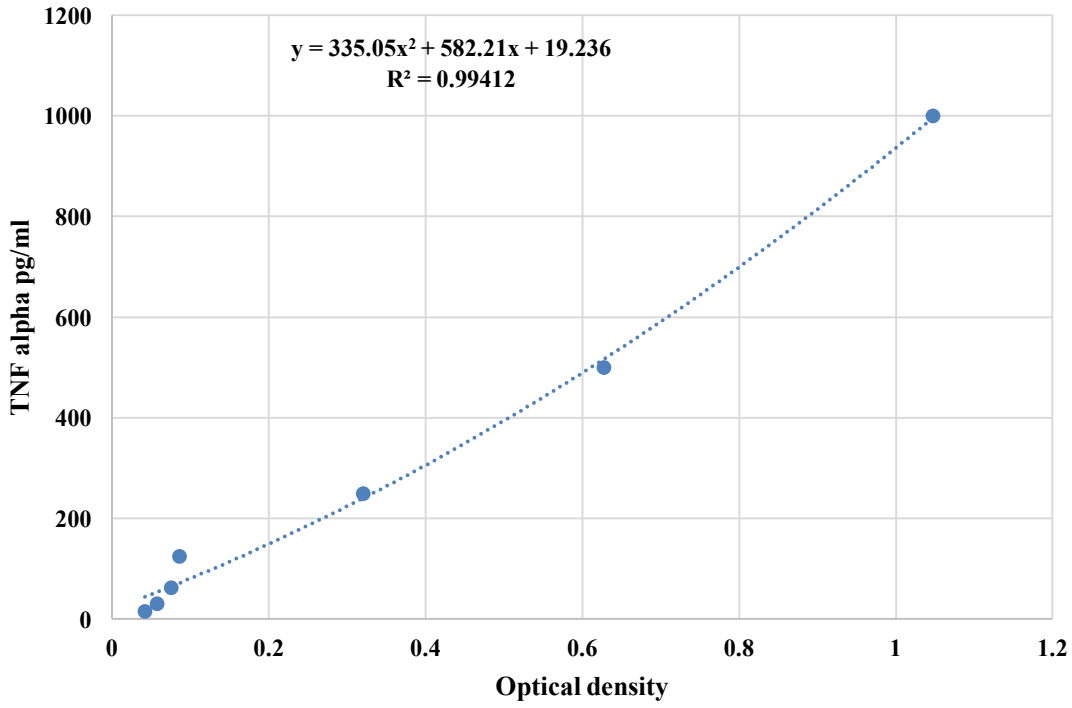
TNF-α standard curve (ELISA 1) for patients (P21-P40)



TNF-α standard curve (ELISA 2) for patients (P21-P40)

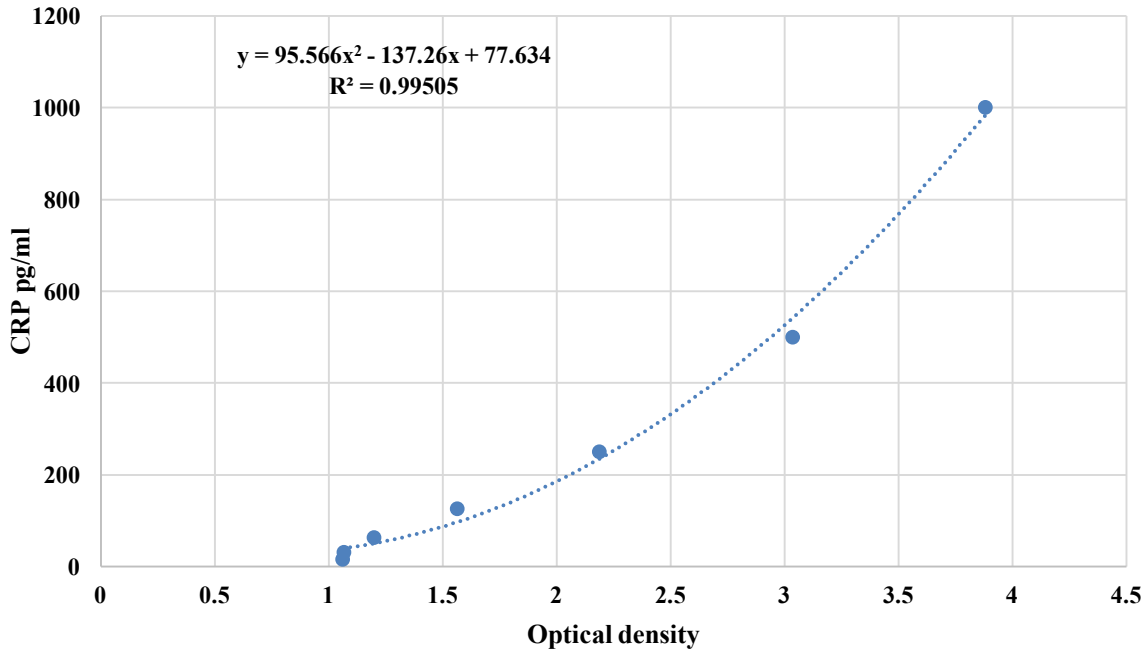


TNF-α standard curve (ELISA 1) for patients (P41-P52)

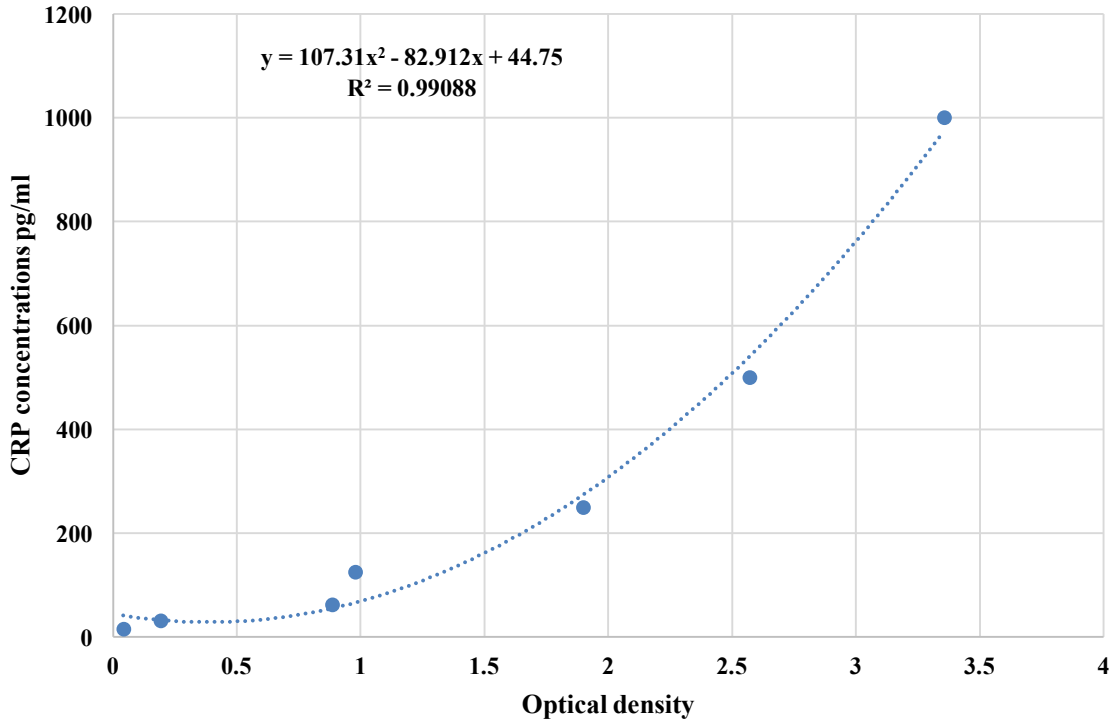


TNF-α standard Curve (ELISA 2)for patients (P41-P52)

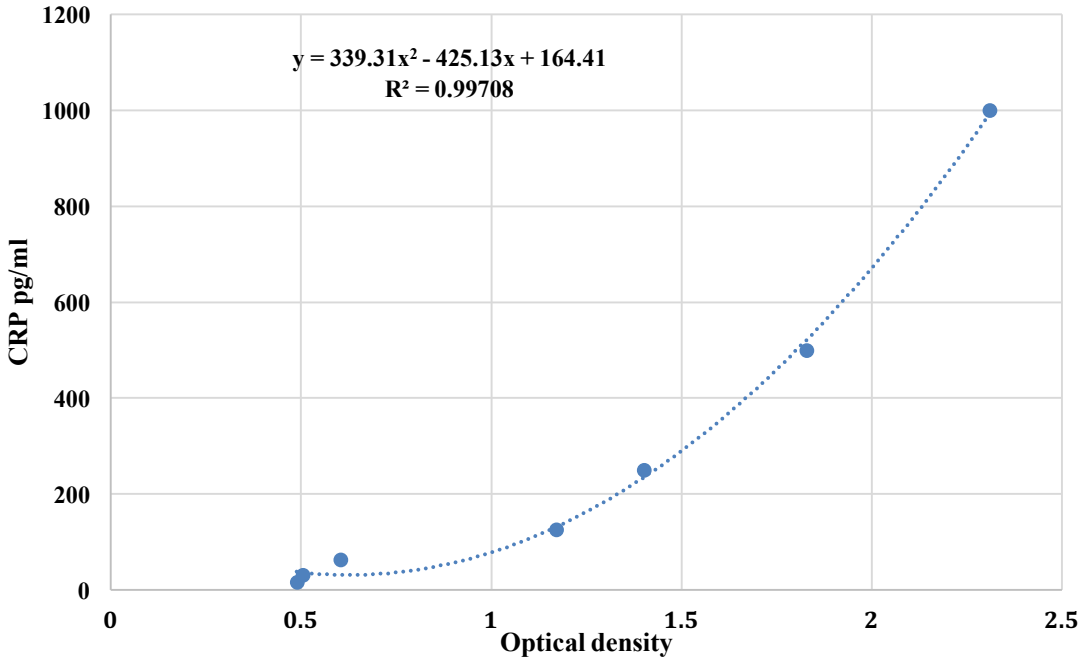
Appendix G: CRP standard curves for all patients' samples



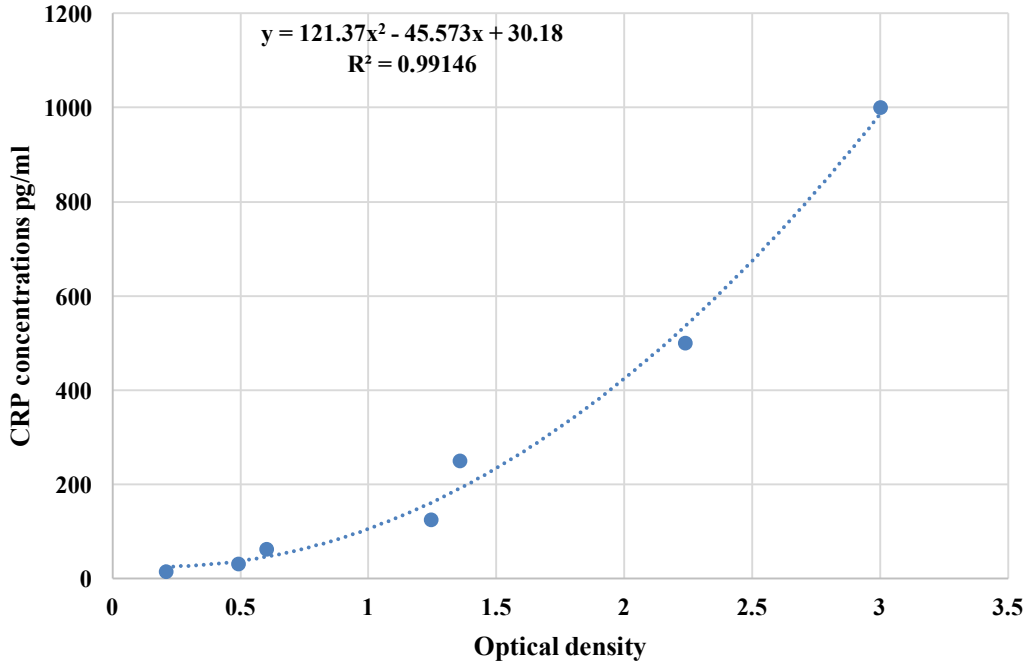
CRP standard curve (ELISA 2) for Patients(P1-P20)



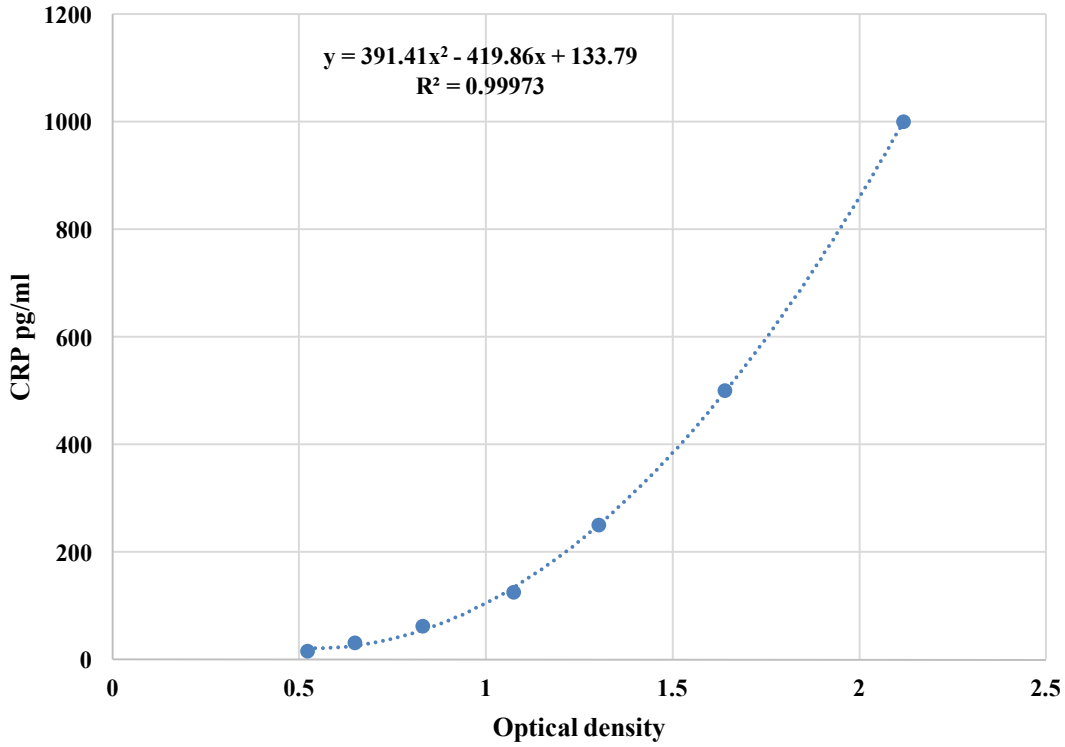
CRP standard curve (ELISA 1) for patients (P21-P40)



CRP standard Curve (ELISA 2) for patients (P21-P40)



CRPstandard curve (ELISA 1) for patients(P41-P52)



CRP standard Curve (ELISA 2) for paitents (P41-P52)

Appendix H : Clinical study (Patients' ELISA data)
